Estimating volatility: EWMA and GARCH(1,1)

Maximum Likelihood methods

Using GARCH (1, 1) model to forecast volatility

Correlations

Extensions of GARCH

- The goal of this chapter is to explain how historical data can be used to produce estimates of the current and future levels of volatilities and correlations.
- This problem is relevant both for the calculation of risk measures (such as Value-at-Risk) and for the valuation of derivatives.
- We consider the following three models:
  - (i) the exponentially weighted moving average (EWMA) model;
  - (ii) the autoregressive conditional heteroscedascity (ARCH) model;
  - (iii) the generalized ARCH (GARCH) model.
- The distinctive feature is that these models recognize that volatilities and correlations are not constant.
- During some periods, a particular volatility or correlation may be relatively low, whereas during other periods it may be relatively high.
- The models attempt to keep track of the variations in the volatility or correlation through time.

## Introduction

- To estimate the volatility of a stock from (empirical) data, the price of the stock is observed at fixed intervals of time (e.g. every day, week, or month).
- Consider

$n + 1$  : number of observations

$S_i$  : stock price at the end of the  $i^{\text{th}}$  interval, with  $i = 0, 1, \dots, n$

$\tau$  : length of the time intervals in years

and let

$$u_i = \log \left( \frac{S_i}{S_{i-1}} \right) \quad i = 1, 2, \dots, n.$$

- The usual estimate  $s$  of the standard deviation of the  $u_i$ 's is given by

$$s = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (u_i - \bar{u})^2},$$

where  $\bar{u}$  is the sample mean of  $u_i$ .

- The annualized volatility  $\sigma$  can be estimated as  $\hat{\sigma} = \frac{s}{\sqrt{\tau}}$
- The standard error of this estimate can be shown to be approximately  $\hat{\sigma}/(\sqrt{2n})$ .

- Choosing an appropriate value for  $n$  is not easy.
- More data generally leads to more accuracy, but  $\sigma$  does change over time and data that is too old may not be relevant for predicting the future volatility.
- A compromise that seems to work reasonably well is to use closing prices from daily data over the most recent 90 to 180 days.
- An often used rule of thumb is to set  $n$  equal to the number of days to which the volatility is applied.
- Thus, if the volatility estimate is used to value a 2-year option, daily data for the last 2 years are used.

A sequence of stock prices during 21 consecutive trading days:

In this case

$$\sum u_i = 0.09531 \quad \text{and} \quad \sum u_i^2 = 0.00326$$

## Introduction: Example

- The estimate of the standard deviation of daily returns is

$$\sqrt{\frac{0.00326}{19} - \frac{0.09531^2}{20 \cdot 19}} = 0.01216 \quad \text{or} \quad 1.216\%.$$

- Assuming that there are 252 trading days per year, i.e.,  $\tau = 1/252$ , an estimate for the volatility per annum is

$$0.01216 \times \sqrt{252} = 0.193 \quad \text{or} \quad 19.3\%.$$

- The standard error of this estimate is

$$\frac{0.193}{\sqrt{2 \times 20}} = 0.031 \quad \text{or} \quad 3.1\% \quad \text{per annum.}$$

- With dividend paying stocks: the return  $u_i$  during a time interval that includes an ex-dividend day is given by

$$u_i = \log \frac{S_i + D_i}{S_{i-1}}$$

where  $D_i$  is the amount of the dividend at time  $i$ .

- An important issue is whether time should be measured in calendar days or trading days when volatility parameters are being estimated and used.
- Practitioners tend to ignore days on which the exchange is closed when estimating volatility from historical data (and when calculating the life of an option).
- The volatility per annum is calculated from the volatility per trading day using the formula

$$\text{Vol per annum} = \text{Vol per tr. day} \times \sqrt{\text{nr. of tr. days per annum.}}$$

- It is natural to assume that the volatility of a stock is caused by new information reaching the market.
- New information causes people to revise their opinions about the value of the stock: the price of the stock changes and volatility results.
- With several years of daily stock price data researchers have calculated:
  - (i) the variance of the stock price returns between the close of trading on one day and the close of trading on the next day when there are no intervening non-trading days (in fact a variance of returns over a 1-day period);
  - (ii) the variance of the stock price returns between the close of trading on Friday and the close of trading on Monday (in fact a variance of returns over 3-day period).

## Introduction: What causes volatility?

- We might be tempted to expect the second variance to be three times as great as the first variance but this is not the case (Fama 1965, French 1980, French and Roll 1980: second variance is, respectively, only 22%, 19% and 10.7% higher than the first variance).
- It seems that volatility is to a large extent caused by trading itself.

## 1 Estimating volatility and correlations

Introduction

Estimating volatility: EWMA and GARCH(1,1)

Maximum Likelihood methods

Using GARCH (1, 1) model to forecast volatility

Correlations

Extensions of GARCH

## Estimating volatility

- Define  $\sigma_n$  the volatility of a market variable on day  $n$ , as estimated at the end of day  $n - 1$ .
- The square of the volatility  $\sigma_n^2$  on day  $n$  is the variance rate.
- Recall that the variable  $u_i$  is defined as the continuously compounded return between the end of day  $i - 1$  and the end of day  $i$ :

$$u_i = \log \frac{S_i}{S_{i-1}}.$$

- An unbiased estimate of the variance rate per day,  $\sigma_n^2$ , using the most recent  $m$  observations on the  $u_i$  is

$$\sigma_n^2 = \frac{1}{m-1} \sum_{i=1}^m (u_{n-i} - \bar{u})^2$$

where the mean  $\bar{u}$  is given by

$$\bar{u} = \frac{1}{m} \sum_{i=1}^m u_{n-i}.$$

## Estimating volatility

- For the purposes of monitoring daily volatility the last formula is usually changed in a number of ways

- (i)  $u_i$  is defined as the percentage change in the market variable between the end of day  $i - 1$  and the end of day  $i$ , so that

$$u_i = \frac{S_i - S_{i-1}}{S_{i-1}};$$

- (ii)  $\bar{u}$  is assumed to be zero;
- (iii)  $m - 1$  is replaced by  $m$ .

- These three changes make very little difference to the estimates that are calculated but they allow us to simplify the formula for the variance rate to

$$\sigma_n^2 = \frac{1}{m} \sum_{i=1}^m u_{n-i}^2.$$

- The last expression gives equal weight to  $u_{n-1}^2, u_{n-2}^2, \dots, u_{n-m}^2$ .
- Our objective is to estimate the current level of volatility  $\sigma_n$ , therefore it makes sense to give more weight to recent data.

- We can accomplish this with a model that sets:

$$\sigma_n^2 = \sum_{i=1}^m \alpha_i u_{n-i}^2. \quad (1)$$

- The coefficient  $\alpha_i > 0$  is the weight given to the observation  $i$  days ago.
- If we choose them so that  $\alpha_i < \alpha_j$  when  $i > j$ , less weight is given to older observations.
- The weights must sum up to unity, so we have

$$\sum_{i=1}^m \alpha_i = 1.$$

## Estimating volatility

- An extension of the idea in Eq. (1) is to assume that there is a long-run average variance rate and that this should be given some weight.
- This leads to a model that takes the form

$$\sigma_n^2 = \gamma V_L + \sum_{i=1}^m \alpha_i u_{n-i}^2, \quad (2)$$

where  $V_L$  is the long-run variance rate and  $\gamma$  is the weight assigned to  $V_L$ .

- Because the weights must sum to unity, we have

$$\gamma + \sum_{i=1}^m \alpha_i = 1.$$

## Estimating volatility

- This is known as an ARCH( $m$ ) model and it was first suggested by Robert Engle in 1982.
- The estimate of the variance is based on a long-run average variance and  $m$  observations: the older an observation, the less weight it is given.
- Defining  $\omega = \gamma V_L$  the model in Eq. (2) can be written as

$$\sigma_n^2 = \omega + \sum_{i=1}^m \alpha_i u_{n-i}^2.$$

- This is the version of the model used when the parameters are estimated.

- The exponentially weighted moving average (EWMA) model is a particular case of the model in Eq. (1) where the weights  $\alpha_i$  decrease exponentially as we move back through time.
- Specifically  $\alpha_{i+1} = \lambda\alpha_i$  where  $\lambda$  is a constant between 0 and 1.
- It turns out that this weighting scheme leads to a particularly simple formula for updating volatility estimates:

$$\sigma_n^2 = \lambda\sigma_{n-1}^2 + (1 - \lambda)u_{n-1}^2. \quad (3)$$

- The estimate  $\sigma_n$  is the volatility for day  $n$  (made at the end of day  $n - 1$ ) is calculated from  $\sigma_{n-1}$  (the estimate that was made at the end of day  $n - 2$  of the volatility for day  $n - 1$ ) and  $u_{n-1}$  (the most recent percentage change).

## The EWMA model

- To understand why Eq. (3) corresponds to weights that decrease exponentially, we substitute for  $\sigma_{n-1}^2$  to get

$$\sigma_n^2 = \lambda[\lambda\sigma_{n-2}^2 + (1 - \lambda)u_{n-2}^2] + (1 - \lambda)u_{n-1}^2,$$

or

$$\sigma_n^2 = (1 - \lambda)(u_{n-1}^2 + \lambda u_{n-2}^2) + \lambda^2 \sigma_{n-2}^2.$$

- Substituting in a similar way for  $\sigma_{n-2}^2$  gives

$$\sigma_n^2 = (1 - \lambda)(u_{n-1}^2 + \lambda u_{n-2}^2 + \lambda^2 u_{n-3}^2) + \lambda^3 \sigma_{n-3}^2.$$

- Continuing in this way we see that

$$\sigma_n^2 = (1 - \lambda) \sum_{i=1}^m \lambda^{i-1} u_{n-i}^2 + \lambda^m \sigma_{n-m}^2.$$

- Recall

$$\sigma_n^2 = (1 - \lambda) \sum_{i=1}^m \lambda^{i-1} u_{n-i}^2 + \lambda^m \sigma_{n-m}^2. \quad (4)$$

- For large  $m$  the term  $\lambda^m \sigma_{n-m}^2$  is sufficiently small to be ignored so that Eq. (4) is the same as Eq. (1) with  $\alpha_i = (1 - \lambda)\lambda^{i-1}$ .
- The weights for the  $u_i$  decline at rate  $\lambda$  as we move back through time; each weight is  $\lambda$  times the previous weight.

## The EWMA model: Example

- Suppose that  $\lambda = 0.90$ , the volatility estimated for a market variable for day  $n - 1$  is 1% per day and during day  $n - 1$  the market variable increased by 2%.
- This means  $\sigma_{n-1}^2 = 0.01^2 = 0.0001$  and  $u_{n-1}^2 = 0.02^2 = 0.0004$ .
- Eq. (3) gives

$$\sigma_n^2 = 0.9 \times 0.0001 + 0.1 \times 0.0004 = 0.00013.$$

- The estimate of the volatility  $\sigma_n$  for day  $n$  is therefore  $\sqrt{0.00013}$  or 1.14% per day.
- Note that the expected value of  $u_{n-1}^2$  is  $\sigma_{n-1}^2$  or 0.0001.
- In this example, the realized value of  $u_{n-1}^2$  is greater than the expected value and as a result our volatility estimate increases.
- If the realized value of  $u_{n-1}^2$  had been less than its expected value, our estimate of the volatility would have decreased.

## The EWMA model

- The EWMA approach has the attractive feature that relatively little data needs to be stored.
- At any given time we need to remember only the current estimate of the variance rate and the most recent observation on the value of the market variable.
- When we get a new observation on the value of the market variable, we calculate a new daily percentage change and use Eq. (3) to update our estimate of the variance rate.
- The old estimate of the variance rate and the old value of the market variable can then be discarded.
- The EWMA approach is designed to track changes in the volatility.
- The Risk Metrics database, which was originally created by J. P. Morgan and made publicly available in 1994, uses the EWMA model with  $\lambda = 0.94$  for updating daily volatility estimates.
- The company found that, across a range of different market variables, this value of  $\lambda$  gives forecasts of the variance rate that come closest to the realized variance rate.

## The GARCH(1,1) model

- Proposed by T. Bollerslev in 1986.
- The difference between GARCH(1,1) and EWMA is analogous to the difference between Eq. (1) and Eq. (2).
- In GARCH(1,1)  $\sigma_n^2$  is calculated from the long-run average variance rate  $V_L$  as well as from  $\sigma_{n-1}$  and  $u_{n-1}$ .
- The equation for GARCH(1,1) is

$$\sigma_n^2 = \gamma V_L + \alpha u_{n-1}^2 + \beta \sigma_{n-1}^2,$$

where  $\gamma$  is the weight assigned to  $V_L$ ,  $\alpha$  is the weight assigned to  $u_{n-1}^2$  and  $\beta$  is the weight assigned to  $\sigma_{n-1}^2$ .

- The weights sum up to one

$$\gamma + \alpha + \beta = 1.$$

## The GARCH(1,1) model

- The EWMA model is a particular case of GARCH(1,1) where  $\gamma = 0$ ,  $\alpha = 1 - \lambda$ ,  $\beta = \lambda$ .
- The (1,1) in GARCH(1,1) indicates that  $\sigma_n^2$  is based on the most recent observation of  $u^2$  and the most recent estimate of the variance rate.
- The more general GARCH(p,q) model calculates  $\sigma_n^2$  from the most recent  $p$  observations of  $u^2$  and the most recent  $q$  estimates of the variance rate; GARCH(1,1) is by far the most popular of the GARCH models.
- Setting  $\omega = \gamma V_L$ , the GARCH(1,1) model can also be written as

$$\sigma_n^2 = \omega + \alpha u_{n-1}^2 + \beta \sigma_{n-1}^2. \quad (5)$$

- The last form is usually used for the purposes of estimating the parameters.
- For a stable GARCH(1,1) process we require  $\alpha + \beta < 1$ , otherwise the weight term applied to the long-term variance is negative.

## The GARCH(1,1) model: Example

- Suppose that a GARCH(1,1) model is estimated from daily data as

$$\sigma_n^2 = 0.000002 + 0.13u_{n-1}^2 + 0.86\sigma_{n-1}^2.$$

- This corresponds to  $\alpha = 0.13$ ,  $\beta = 0.86$  and  $\omega = 0.000002$ .
- Because  $\gamma = 1 - \alpha - \beta$  it follows that  $\gamma = 0.01$ .
- Because  $\omega = \gamma V_L$  it follows that  $V_L = 0.0002$ .
- In other words, the long-run average variance per day implied by the model is 0.0002.
- This corresponds to a volatility of  $\sqrt{0.0002} = 0.014$  or 1.4% per day.
- Suppose that the estimate of the volatility on day  $n - 1$  is 1.6% per day, so that  $\sigma_{n-1}^2 = 0.016^2 = 0.000256$  and that on day  $n - 1$  the market variable decreased by 1% so that  $u_{n-1}^2 = 0.01^2 = 0.0001$ .
- Then

$$\sigma_n^2 = 0.000002 + 0.13 \times 0.0001 + 0.86 \times 0.000256 = 0.00023516.$$

- The new estimate of the volatility is therefore  $\sqrt{0.00023516} = 0.0153$  or 1.53%.

## The GARCH(1,1) model: The weights

- Substituting for  $\sigma_{n-1}^2$  and, afterwards, for  $\sigma_{n-2}^2$  in Eq. (5), we get

$$\sigma_n^2 = \omega + \beta\omega + \beta^2\omega + \alpha u_{n-1}^2 + \alpha\beta u_{n-2}^2 + \alpha\beta^2 u_{n-3}^2 + \beta^3 \sigma_{n-3}^2.$$

- Continuing in this way we see that the weight applied to  $u_{n-i}^2$  is  $\alpha\beta^{i-1}$ .
- The weights decline exponentially at rate  $\beta$ .
- The parameter  $\beta$  can be interpreted as decay rate; it is similar to the  $\lambda$  in the EWMA model.
- The GARCH(1,1) model is similar to the EWMA model except that, in addition to assign weights that decline exponentially to past  $u^2$  it also assigns some weight to the long-run average volatility.

## The GARCH(1,1) model: Mean reversion (optional part)

- The GARCH(1,1) model recognizes that over time the variance tends to get pulled back to a long-run average level of  $V_L$ .
- The amount of weight assigned to  $V_L$  is  $\gamma = 1 - \alpha - \beta$ .
- The GARCH(1,1) is equivalent to a model where the variance  $V$  follows the stochastic process

$$dV = a(V_L - V)dt + \xi V dz$$

where time is measured in days,  $a = 1 - \alpha - \beta$  and  $\xi = \alpha\sqrt{2}$ ; this is the mean reverting model.

- The variance has a drift that pulls it back to  $V_L$  at rate  $a$ .
- When  $V > V_L$ , the variance has a negative drift; when  $V < V_L$  it has a positive drift.

## Choosing between the models

- In practice variance rates tend to be mean reverting.
- The GARCH(1,1) model incorporates mean reversion, whereas the EWMA model does not.
- GARCH(1,1) is therefore more appealing than the EWMA model.
- A question that needs to be discussed is how best-fit parameters  $\omega$ ,  $\alpha$ ,  $\beta$  in GARCH(1,1) can be estimated.
- When the parameter  $\omega$  is zero, the GARCH(1,1) reduces to EWMA.
- In circumstances where the best-fit value of  $\omega$  turns out to be negative, the GARCH(1,1) model is not stable and it makes sense to switch to the EWMA model.

- How are the parameters estimated from historical data in the models we have been considering?
- A commonly applied approach is known as the maximum likelihood (ML) method.
- It involves choosing values for the parameter that maximize the chance (or likelihood) of the data occurring.

- Suppose we have a sample  $x_1, x_2, \dots, x_N$  of  $N$  i.i.d. random variables, coming from a parametric model.
- The joint density function of the observations is

$$f(x_1, x_2, \dots, x_N | \theta) = f_1(x_1 | \theta) \cdot f_2(x_2 | \theta) \cdot \dots \cdot f_n(x_N | \theta),$$

where  $\theta$  summarises the model parameters.

- The idea of the maximum likelihood (ML) method is to choose  $\theta$  such that the joint density function is maximised, given the observed sample of data.
- A natural tool to this end is the likelihood function, which we define as

$$\mathcal{L}(\theta | x_1, x_2, \dots, x_N) := f(x_1, x_2, \dots, x_N | \theta) = \prod_{i=1}^N f_i(x_i | \theta).$$

- To convert the product to summation (which is easier to handle on a computer), we take the logarithm. The result is called the log-likelihood:

$$\log \mathcal{L}(\theta | x_1, x_2, \dots, x_n) = \sum_{i=1}^n \log(f_i(x_i | \theta)).$$

- The ML method estimates  $\theta$  by finding a value for  $\theta$  that maximises  $\log \mathcal{L}(\theta | x_1, x_2, \dots, x_n)$ , i.e.,

$$\hat{\theta}_{\text{MLE}} := \arg \max_{\theta} \log \mathcal{L}(\theta | x_1, x_2, \dots, x_n).$$

## Estimating a constant variance

- Problem: estimate the variance of a variable  $X$  from  $m$  observations on  $X$  when the underlying distribution is normal with zero mean.
- Let  $u_1, u_2, \dots$  denote the sample of  $m$  observations.
- Denote the unknown variance parameter by  $v$ .
- The likelihood of  $u_i$  being observed is the probability density function for  $X$  when  $X = u_i$

$$\frac{1}{\sqrt{2\pi v}} \exp\left(\frac{-u_i^2}{2v}\right).$$

- The likelihood of  $m$  observations occurring in order in which they are observed is

$$\prod_{i=1}^m \left[ \frac{1}{\sqrt{2\pi v}} \exp\left(\frac{-u_i^2}{2v}\right) \right].$$

- Using the maximum likelihood method, the best estimate of  $v$  is the value that maximizes this expression.

## Estimating a constant variance

- Maximizing an expression is equivalent to maximizing the logarithm of the expression.
- Taking logarithms and ignoring constant multiplicative factors, it can be seen that we wish to maximize

$$\sum_{i=1}^m \left[ -\log v - \frac{u_i^2}{v} \right].$$

- Differentiating this expression with respect to  $v$  and setting the result equation to zero, we see that the maximum likelihood estimator of  $v$  is

$$\frac{1}{m} \sum_{i=1}^m u_i^2.$$

## Estimating GARCH(1,1) parameters

- How can the likelihood method be used to estimate the parameters when the GARCH(1,1) method or some other volatility update scheme is used?
- Define  $v_i = \sigma_i^2$  as the variance estimated for day  $i$ .
- We assume that the probability distribution of  $u_i$  conditional on the variance is normal.
- A similar analysis to the one just given shows that the best parameters are the ones that maximize

$$\prod_{i=1}^m \left[ \frac{1}{\sqrt{2\pi v_i}} \exp\left(\frac{-u_i^2}{2v_i}\right) \right].$$

- This is equivalent (taking logarithms) to maximizing

$$\sum_{i=1}^m \left[ -\log v_i - \frac{u_i^2}{v_i} \right]. \quad (6)$$

- This is the same expression as above, except that  $v$  is replaced by  $v_i$ .
- We search iteratively to find the parameters of the model that maximize the expression in (6).

## Estimation of GARCH(1,1) parameters: Example

- The fifth column shows the estimate of the variance rate  $v_i = \sigma_i^2$  for day  $i$  made at the end of day  $i - 1$ .
- On day 3 we start things off by setting the variance equal to  $u_2^2$ .
- On subsequent days, we use equation

$$\sigma_n^2 = \omega + \alpha u_{n-1}^2 + \beta \sigma_{n-1}^2.$$

- The sixth column tabulates the likelihood measure  $-\log(v_i) - u_i^2/v_i$ .
- The values in the fifth and sixth columns are based on the current trial estimates of  $\omega$ ,  $\alpha$  and  $\beta$ : we are interested in maximizing the sum of the members in the sixth column.
- This involves an iterative search procedure.
- In our example the optimal values of the parameters turn out to be

$$\omega = 0.00000176, \quad \alpha = 0.0626, \quad \beta = 0.8976.$$

- The numbers shown in the above table were calculated on the final iteration of the search for the optimal  $\omega$ ,  $\alpha$ , and  $\beta$ .
- The long-term variance rate  $V_L$  in our example is

$$\frac{\omega}{1 - \alpha - \beta} = \frac{0.00000176}{0.0398} = 0.00004422.$$

### References

- When the EWMA model is used, the estimation procedure is relatively simple: we set  $\omega = 0$ ,  $\alpha = 1 - \lambda$ , and  $\beta = \lambda$ .
- In the table above, the value of  $\lambda$  that maximizes the objective function is 0.9686 and the value of the objective function is 21995.8377.
- Both GARCH(1,1) and the EWMA method can be implemented by using the solver routine in Excel to search for the values of the parameters that maximize the likelihood function.

Extensions of GARCH

## Using GARCH (1, 1) to forecast future volatility

- The variance rate estimated at the end of day  $n - 1$  for day  $n$ , when GARCH (1,1) is used, is

$$\sigma_n^2 = (1 - \alpha - \beta)V_L + \alpha u_{n-1}^2 + \beta \sigma_{n-1}^2$$

so that

$$\sigma_n^2 - V_L = \alpha(u_{n-1}^2 - V_L) + \beta(\sigma_{n-1}^2 - V_L).$$

- On day  $n + t$  in the future, we have

$$\sigma_{n+t}^2 - V_L = \alpha(u_{n+t-1}^2 - V_L) + \beta(\sigma_{n+t-1}^2 - V_L).$$

- The expected value of  $u_{n+t-1}^2$  is  $\sigma_{n+t-1}^2$ , hence

$$\mathbb{E}[\sigma_{n+t}^2 - V_L] = (\alpha + \beta)\mathbb{E}[\sigma_{n+t-1}^2 - V_L].$$

- Using this equation repeatedly yields

$$\mathbb{E}[\sigma_{n+t}^2 - V_L] = (\alpha + \beta)^t(\sigma_n^2 - V_L)$$

or

$$\mathbb{E}[\sigma_{n+t}^2] = V_L + (\alpha + \beta)^t(\sigma_n^2 - V_L). \quad (7)$$

- This equation forecasts the volatility on day  $n + t$  using the information available at the end of the day  $n - 1$ .

## Using GARCH(1,1) to forecast future volatility

Estimating  
volatility:  
EWMA and  
GARCH(1,1)

Maximum  
Likelihood  
methods

Using GARCH  
(1, 1) model to  
forecast volatility

Correlations

Extensions of  
GARCH

### References

- In the EWMA model  $\alpha + \beta = 1$  and the last equation shows that the expected future variance rate equals the current variance rate.
- When  $\alpha + \beta < 1$  the final term in the equation becomes progressively smaller as  $t$  increases.
- As mentioned earlier, the variance rate exhibits mean reversion with a reversion level of  $V_L$  and a reversion rate of  $1 - \alpha - \beta$ .
- Our forecast of the future variance rate tends towards  $V_L$  as we look further and further ahead.
- This analysis emphasizes the point that we must have  $\alpha + \beta < 1$  for a stable GARCH(1,1) process.
- When  $\alpha + \beta > 1$  the weight given to the long-term average variance is negative and the process is mean fleeing rather than mean reverting.

## Using GARCH(1,1) to forecast future volatility

- In the yen-dollar exchange rare example considered earlier  $\alpha + \beta = 0.9602$  and  $V_L = 0.00004422$ .
- Suppose that our estimate of the current variance rate per day is 0.00006 (this corresponds to a volatility of 0.77% per day).
- In 10 days the expected variance rate is

$$0.00004422 + 0.9602^{10}(0.00006 - 0.00004422) = 0.00005473.$$

- The expected volatility per day is 0.0074, still well above the long-term volatility of 0.00665 per day.
- However the expected variance rate in 100 days is

$$0.00004422 + 0.9602^{100}(0.00006 - 0.00004422) = 0.00004449$$

and the expected volatility per day is 0.00667 very close to the long-term volatility.

## 1 Estimating volatility and correlations

Introduction

Estimating volatility: EWMA and GARCH(1,1)

Maximum Likelihood methods

Using GARCH (1, 1) model to forecast volatility

Correlations

Extensions of GARCH

- The discussion so far has centered on the estimation and forecasting of volatility.
- Correlations play a key role in the computation of VaR.
- The goal of this section is to show how correlation estimates can be updated in a similar way to volatility estimates.

- Recall that the covariance between two random variables  $X$  and  $Y$  is defined as

$$\mathbb{E}[(X - \mu_X)(Y - \mu_Y)]$$

where  $\mu_X$  and  $\mu_Y$  are respectively the means of  $X$  and  $Y$ .

- The correlation between two random variables  $X$  and  $Y$  is

$$\frac{\text{cov}(X, Y)}{\sigma_X \sigma_Y}$$

where  $\sigma_X$  and  $\sigma_Y$  are the two standard deviations of  $X$  and  $Y$  and  $\text{cov}(X, Y)$  is the covariance between  $X$  and  $Y$ .

## Correlations

- Define  $x_i$  and  $y_i$  as the percentage changes in  $X$  and  $Y$  between the end of the day  $i - 1$  and the end of day  $i$ :

$$x_i = \frac{X_i - X_{i-1}}{X_{i-1}} \quad \text{and} \quad y_i = \frac{Y_i - Y_{i-1}}{Y_{i-1}}$$

where  $X_i$  and  $Y_i$  are the values of  $X$  and  $Y$  at the end of the day  $i$ .

- We also define

$\sigma_{x,n}$  : daily volatility of variable  $X$  estimated for day  $n$ ;

$\sigma_{y,n}$  : daily volatility of variable  $Y$  estimated for day  $n$ ;

$cov_n$  : estimate of covariance between daily changes in  $X$  and  $Y$ ,  
calculated on day  $n$ .

- Our estimate of the correlation between  $X$  and  $Y$  on day  $n$  is

$$\frac{cov_n}{\sigma_{x,n}\sigma_{y,n}}.$$

- Using an equal-weighting scheme and assuming that the means of  $x_i$  and  $y_i$  are zero, as before we can estimate the variance rates of  $X$  and  $Y$  from the most recent  $m$  observations as

$$\sigma_{x,n}^2 = \frac{1}{m} \sum_{i=1}^m x_{n-i}^2 \quad \text{and} \quad \sigma_{y,n}^2 = \frac{1}{m} \sum_{i=1}^m y_{n-i}^2.$$

- A similar estimate for the covariance between  $X$  and  $Y$  is

$$\text{cov}_n = \frac{1}{m} \sum_{i=1}^m x_{n-i} y_{n-i}.$$

- One alternative for updating covariances is an EWMA model as previously discussed.
- The formula for updating the covariance estimate is then

$$cov_n = \lambda cov_{n-1} + (1 - \lambda)x_{n-1}y_{n-1}.$$

- A similar analysis to that presented for the EWMA volatility model shows that the weights given to observations on the  $x_i$  and  $y_i$  decline as we move back through time.
- The lower the value of  $\lambda$ , the greater the weight that is given to recent observations.

## Correlations: Example

- Assume  $\lambda = 0.95$  and that the estimate of the correlation between two variables  $X$  and  $Y$  on day  $n - 1$  is 0.6.
- Assume that the estimate of the volatilities for the  $X$  and  $Y$  on day  $n - 1$  are 1% and 2% respectively.
- From the relationship between correlation and covariance, the estimate for the covariance between  $X$  and  $Y$  on day  $n - 1$  is

$$0.6 \times 0.01 \times 0.02 = 0.00012.$$

- Suppose that the percentage changes in  $X$  and  $Y$  on day  $n - 1$  are 0.5% and 2.5% respectively.
- The variance and covariance for day  $n$  would be updated as follows:

$$\sigma_{x,n}^2 = 0.95 \times 0.01^2 + 0.05 \times 0.005^2 = 0.00009625;$$

$$\sigma_{y,n}^2 = 0.95 \times 0.02^2 + 0.05 \times 0.025^2 = 0.00041125;$$

$$\text{cov}_n = 0.95 \times 0.00012 + 0.05 \times 0.005 \times 0.025 = 0.00012025.$$

Estimating  
volatility and  
correlations

Introduction

Estimating  
volatility:  
EWMA and  
GARCH(1,1)

Maximum  
Likelihood  
methods

Using GARCH  
(1, 1) model to  
forecast volatility

Correlations

Extensions of  
GARCH

References

- The new volatility of  $X$  is  $\sqrt{0.00009625} = 0.981\%$ .
- The new volatility of  $Y$  is  $\sqrt{0.00041125} = 2.028\%$ .
- The new coefficient of correlation between  $X$  and  $Y$  is

$$\frac{0.00012025}{0.00981 \times 0.02028} = 0.6044.$$

- GARCH models can also be used for updating covariance estimates and forecasting the future level of covariances.
- For example the GARCH(1,1) model for updating a covariance is

$$cov_n = \omega + \alpha x_{n-1} y_{n-1} + \beta cov_{n-1}$$

and the long-term average covariance is  $\omega / (1 - \alpha - \beta)$ .

- Similar formulas to those discussed above can be developed for forecasting future covariances and calculating the average covariance during the life time of an option.

## Consistency condition for covariances

- Once all the variances and covariances have been calculated, a variance-covariance matrix can be constructed.
- When  $i \neq j$ , the  $(i, j)$  element of this matrix shows the covariance between variable  $i$  and  $j$ ; when  $j = i$  it shows the variance of variable  $i$ .
- Not all variance-covariance matrices are internally consistent; the condition for an  $N \times N$  variance-covariance matrix  $\Omega$  to be internally consistent is

$$w^T \cdot \Omega \cdot w \geq 0$$

for all  $N \times 1$  vectors  $w$ , where  $w^T$  is the transpose of  $w$ ; such a matrix is positive-semidefinite.

- To understand why the last condition must hold, suppose that  $w^T$  is  $(w_1, \dots, w_n)$ ; the expression  $w^T \cdot \Omega \cdot w$  is the variance of  $w_1x_1 + \dots + w_nx_n$  where  $x_i$  is the value of the variable  $i$ ; as such it cannot be negative.

## Consistency condition for covariances

- To ensure that a positive-semidefinite matrix is produced, variances and covariances should be calculated consistently.
- For example, if variances are calculated by giving equal weight to the last  $m$  data items, the same should be done for covariances.
- If variances are updated using an EWMA model with  $\lambda = 0.94$  the same should be done for covariances.
- An example of a variance-covariance matrix that it is not internally consistent is

$$\begin{bmatrix} 1 & 0 & 0.9 \\ 0 & 1 & 0.9 \\ 0.9 & 0.9 & 1 \end{bmatrix}$$

- The variance of each variable is 1.0 and so the covariances are also coefficients of correlation.
- The first variable is highly correlated with the third variable and the second variable is highly correlated with the third variable.
- However there is no correlation at all between the first and the second variables; this seems strange; when we set  $w$  equal to  $(1, 1, -1)$  we find that the positive semi-definiteness condition above is not satisfied proving that the matrix is not positive-semidefinite.

### 1 Estimating volatility and correlations

Introduction

Estimating volatility: EWMA and GARCH(1,1)

Maximum Likelihood methods

Using GARCH (1, 1) model to forecast volatility

Correlations

Extensions of GARCH

## Extensions of GARCH

- Exponential GARCH (EGARCH)
- Threshold GARCH (TGARCH)

## Exponential GARCH (EGARCH)

- The EGARCH model is a GARCH variant that models the logarithm of the conditional variance.
- It includes a leverage term to capture the asymmetric effects between positive and negative asset returns.
- The EGARCH(1,1) model takes the following form:

$$\log \sigma_n^2 = \omega + \alpha g(\epsilon_{n-1}) + \beta \log \sigma_{n-1}^2,$$

where  $\epsilon_n = u_n/\sigma_n$  and  $g(\epsilon_n) = \theta\epsilon_n + \gamma(|\epsilon_n| - E[|\epsilon_n|])$ .

- Since negative returns have a more pronounced effect on volatility than positive returns of the same magnitude, the parameter  $\theta$  usually takes negative values.

## Threshold GARCH (TGARCH)

- The TGARCH model is a specification of conditional variance.
- Like the EGARCH model, it allows positive returns to have a larger/smaller impact on volatility than negative returns.
- The TGARCH(1,1) model has the following form:

$$\sigma_n^2 = \omega + (\alpha + \gamma N_{n-1})u_{n-1}^2 + \beta\sigma_{n-1}^2$$

where  $N_{n-1}$  is an indicator for negative  $u_{n-1}$ , that is

$$N_{n-1} = \begin{cases} 1 & \text{if } u_{n-1} < 0 \\ 0 & \text{if } u_{n-1} \geq 0 \end{cases}$$
