We investigate decompositions of a graph into a small number of low-diameter subgraphs. Let $P(n, \epsilon, d)$ be the smallest k such that every graph $G = (V, E)$ on n vertices has an edge partition $E = E_0 \cup E_1 \cup \cdots \cup E_k$ such that $|E_0| \leqslant \epsilon n^2$, and for all $1 \leqslant i \leqslant k$ the diameter of the subgraph spanned by E_i is at most d. Using Szemerédi's regularity lemma, Polcyn and Ruciński showed that $P(n, \epsilon, 4)$ is bounded above by a constant depending only on ϵ. This shows that every dense graph can be partitioned into a small number of 'small worlds' provided that a few edges can be ignored. Improving on their result, we determine $P(n, \epsilon, d)$ within an absolute constant factor, showing that $P(n, \epsilon, 2) = \Theta(n)$ is unbounded for $\epsilon < 1/4$, $P(n, \epsilon, 3) = \Theta(1/\epsilon^2)$ for $\epsilon > n^{-1/2}$ and $P(n, \epsilon, 4) = \Theta(1/\epsilon)$ for $\epsilon > n^{-1}$. We also prove that if G has large minimum degree, *all the edges* of G can be covered by a small number of low-diameter subgraphs. Finally, we extend some of these results to hypergraphs, improving earlier work of Polcyn, Rödl, Ruciński and Szemerédi.

1. Introduction

The *distance* between two vertices of a graph is the length of the shortest path between them. The *diameter* diam(G) of a connected graph $G = (V, E)$ is the maximum distance between any pair of vertices of the graph. If G is not connected, diam(G) $= \infty$. For an edge subset $E' \subset E$, the diameter of E' is the diameter of the subgraph of G with edge set E', whose vertex set consists of all the vertices of G which belong to at least one edge of E'.

Extremal problems on the diameter of graphs have a long history and were first investigated by Erdős and Rényi [5] and Erdős, Rényi and Sós [6], who studied the

minimum number of edges in an n-vertex graph with diameter at most d. Another line of research concerning the change of diameter if edges of the graph are added or deleted was initiated by Chung and Garey [2] (see also, *e.g.*, [3, 1]). In this paper, we investigate decompositions of a graph into a small number of subgraphs of low diameter. A motivation for such decompositions comes from distributed computing. We are given a set of processors (vertices) with communication channels (edges) between pairs of processors. A fundamental problem when designing algorithms on such systems is determining how much coordination must be done between the processors and accomplishing this coordination as efficiently as possible. The simplest approach is to centralize the network by appointing one processor to coordinate the actions of the network. This approach often simplifies the problem and leads to distributed algorithms based on known serial algorithms. However, if the network has large diameter, such rigid centralization can degrade system performance due to delays in communication. One solution to this problem is to partition the network into regions of low diameter. This approach was used, for example, by Linial and Saks [9], who showed that every graph on n vertices can be vertex-partitioned into $O(\log n)$ induced subgraphs whose connected components have diameter $O(\log n)$.

In this paper we will consider another variant of the low-diameter decomposition problem, which was also studied by several researchers. In this problem the goal is to partition nearly all the edges of a graph into a small number of low-diameter subgraphs. More precisely, we study the following parameter.

Definition 1. For $\epsilon \leqslant 1/2$, let $P(n, \epsilon, d)$ be the smallest ℓ such that every graph $G = (V, E)$ on n vertices has an edge partition $E = E_0 \cup E_1 \cup \cdots \cup E_\ell$ such that $|E_0| \leqslant \epsilon n^2$ and the diameter of E_i is at most d for $1 \leqslant i \leqslant \ell$.

Polcyn and Ruciński [12] recently showed that every dense graph can be partitioned into a small number of 'small worlds' provided that a small fraction of the edges can be ignored. Specifically, they proved that $P(n, \epsilon, 4)$ is bounded by a constant depending only on ϵ. Their proof relies on Szemerédi's regularity lemma and consequently gives an enormous upper bound on $P(n, \epsilon, 4)$ as a function of ϵ, *i.e.*, it shows that $P(n, \epsilon, 4)$ can be bounded from above by a tower of 2s of height polynomial in $1/\epsilon$. One of our main results determines $P(n, \epsilon, d)$ up to a constant factor. It improves on the result of Polcyn and Ruciński both on the diameter bound and on the number of parts.

Theorem 1.1.

(a) *For $\epsilon < 1/4$ bounded away from $1/4$, we have $P(n, \epsilon, 2) = \Theta(n)$.*
(b) *For $\epsilon \geqslant n^{-1/2}$, we have $P(n, \epsilon, 3) = \Theta(1/\epsilon^2)$.*
(c) *For $\epsilon \geqslant n^{-1}$ and $d \geqslant 4$, we have $P(n, \epsilon, d) = \Theta(1/\epsilon)$.*

There is a sharp transition in the behaviour of the function $P(n, \epsilon, 2)$ at $\epsilon = 1/4$, namely $P(n, 1/4, 2) = 1$. Note also that $P(n, \epsilon, 1)$ is the minimum number of edge-disjoint cliques needed to cover all but ϵn^2 edges in any graph on n vertices. This parameter is not so

interesting to study, since, for ϵ not too large, $P(n, \epsilon, 1)$ is quadratic in n, which is seen by considering the complete bipartite graph with parts of equal size.

Extremal problems on the diameter of graphs with large minimum degree have also been studied. For example, Erdős, Pach, Pollack and Tuza [4], answering a question of Gallai, determine up to an additive constant the largest possible diameter of a connected graph with a given number n of vertices and minimum degree δ. The answer is within an additive constant of $\frac{3n}{\delta+1}$. For graphs with large minimum degree, we can show that *all* edges of such graphs can be covered by a small number of low-diameter subgraphs (which are not necessarily edge-disjoint).

Definition 2. For $\epsilon < 1$, let $Q(n, \epsilon, d)$ be the minimum ℓ such that the edges of any graph $G = (V, E)$ on n vertices with minimum degree at least ϵn can be covered by ℓ sets $E = E_1 \cup \cdots \cup E_\ell$ such that the diameter of each E_i is at most d.

We prove the following two results, in which we use the properties of Kneser graphs to establish lower bounds.

Theorem 1.2.

(a) *For fixed* $0 < \epsilon \leqslant 2^{-8}$, *both* $Q(n, \epsilon, 3)$ *and* $Q(n, \epsilon, 4)$ *have order of magnitude* $\Theta(\log n)$.
(b) *For* $\epsilon = \Omega\big((\log n)^{-1/3}\big)$, *we have* $Q(n, \epsilon, 5) = \Theta(1/\epsilon^2)$.
(c) *For* $\epsilon > n^{-1}$ *and* $d \geqslant 6$, *we have* $Q(n, \epsilon, d) = \Theta(1/\epsilon)$.

Note that any graph on n vertices of minimum degree more than $\frac{n}{2} - 1$ has diameter at most 2, since non-adjacent vertices must have a common neighbour. In sharp contrast with Theorem 1.2(a), this shows that $Q(n, 1/2, 2) = 1$.

An analogous problem for hypergraphs was first investigated by Polcyn, Rödl, Ruciński and Szemerédi [11]. A hypergraph $G = (V, E)$ is *k-uniform* if each edge has exactly k vertices. A (tight) *path* of length ℓ in a k-uniform hypergraph $G = (V, E)$ is a subhypergraph consisting of $\ell + k - 1$ vertices $v_1, \dots, v_{\ell+k-1}$ and ℓ edges, such that, for each $i \leqslant \ell$, $(v_i, v_{i+1}, \dots, v_{i+k-1})$ is an edge of G. The vertices v_1 and $v_{\ell+k-1}$ are the endpoints of the path. The *diameter* diam(G) of G is the maximum over all pairs v, w of vertices of the length of the shortest path whose endpoints are v and w. For an edge subset $E' \subset E$, the diameter of E' is the diameter of the subhypergraph of G with edge set E', whose vertex set consists of all the vertices of G which belong to at least one edge of E'.

Definition 3. Let $P_k(n, \epsilon, d)$ be the smallest ℓ such that every k-uniform hypergraph $G = (V, E)$ on n vertices has an edge partition $E = E_0 \cup E_1 \cup \cdots \cup E_\ell$, such that $|E_0| \leqslant \epsilon n^k$ and the diameter of E_i is at most d for $1 \leqslant i \leqslant \ell$.

Polcyn, Rödl, Ruciński and Szemerédi [11] showed that $P_3(n, \epsilon, 12)$ is bounded above by a constant $C_3(\epsilon)$ depending only on ϵ. Their proof uses the hypergraph regularity lemma, and gives an Ackermann-type upper bound on $C_3(\epsilon)$. Here we improve the diameter bound from 12 to 3, which is best possible, generalize it to any uniformity k, and further

show that this function is polynomial in ϵ^{-1}. The proof uses similar counting arguments as done in the graph case.

Theorem 1.3.

(a) *For $\epsilon \gg n^{-2^{1-k}}$, we have $P_k(n, \epsilon, 3) = O(\epsilon^{2-2^k})$.*
(b) *For $\epsilon \gg n^{-1/2}$, we have $P_k(n, \epsilon, 3) \geqslant c_k \epsilon^{-k}$.*

We think the lower bound on $P_k(n, \epsilon, 3)$ in the above theorem is tight.

We study $P(n, \epsilon, d)$ in the next section, where we consider the cases $d = 2, 3, 4$ in three separate subsections. In Section 3, we study edge partitions of graphs of large minimum degree into a small number of low-diameter subgraphs. In Section 4, we prove bounds on $P_k(n, \epsilon, d)$. The last section of the paper contains some concluding remarks and open questions. Throughout the paper, we systematically omit floor and ceiling signs whenever they are not crucial for the sake of clarity of presentation. We also do not make any serious attempt to optimize absolute constants in our statements and proofs. All logarithms in this paper are in base 2 unless explicitly stated as a natural logarithm.

2. Proof of Theorem 1.1

In this section, we prove bounds on $P(n, \epsilon, d)$. We consider the cases $d = 2, 3, 4$ in separate subsections.

2.1. Decomposing a graph into diameter 2 subgraphs

In this subsection we prove Theorem 1.1(a), which states that if $\epsilon < 1/4$ is bounded away from $1/4$, then $P(n, \epsilon, 2) = \Theta(n)$. The proofs for both the upper bound and the lower bound are quite simple. We first show the upper bound. Let G be a graph with n vertices. Note that a star has diameter at most 2. Letting E_i be those edges that contain the ith vertex of G, we have $P(n, 0, 2) \leqslant n$.

To prove the lower bound we use the following simple fact. If G is a bipartite graph, then any subgraph of G which is not complete has diameter at least 3. Indeed, if there is a pair of vertices in different classes that are not adjacent, then the shortest path between them is of odd length greater than 1, and so the diameter is at least 3. We show next that if G is a random bipartite graph of edge density bounded away from 1, then almost surely every complete bipartite subgraph of G has $O(n)$ edges. The *random bipartite graph* $G(n, n, p)$ is the probability space of labelled bipartite graphs with n vertices in each class, where each of the n^2 edges appears independently with probability p. The term *almost surely* means with probability tending to 1 as n tends to infinity.

Lemma 2.1. *Fix $0 < p < 1$ and let $q = 1 - p$. Almost surely, all complete bipartite subgraphs of the random bipartite graph $G = G(n, n, p)$ have at most $2n/q$ edges.*

Proof. Let A and B be the two vertex classes of G. The probability that there exist $S \subset A$ and $T \subset B$ that are complete to each other and have at least $2n/q$ edges between them is

at most

$$p^{2n/q}2^{2n} = (1-q)^{2n/q}2^{2n} \leqslant e^{-2n}2^{2n} = o(1). \qquad \square$$

The Chernoff bound for the binomial distribution implies that the random graph $G(n, n, p)$ almost surely has $pn^2 + o(n^2)$ edges. Let $\epsilon < 1/4$, $q = \frac{1}{4} - \epsilon$ and $p = \frac{3}{4} + \epsilon$. By considering $G(n/2, n/2, p)$, we have that there is a bipartite graph G on n vertices with at least $(p - o(1))n^2/4 = \left(\epsilon + \frac{3}{4}q - o(1)\right)n^2$ edges and such that every diameter 2 subgraph of G has at most n/q edges. To cover $\left(\frac{3}{4}q - o(1)\right)n^2 > qn^2/2$ edges of G by diameter 2 subgraphs, we need to use at least $\frac{qn^2/2}{n/q} = q^2 n/2$ subgraphs. Hence $P(n, \epsilon, 2) \geqslant q^2 n/2 = \frac{(1-4\epsilon)^2}{32} n$ for n sufficiently large. This completes the proof of Theorem 1.1(a). $\qquad \square$

We conclude this subsection by showing that a sharp transition for $P(n, \epsilon, 2)$ occurs at $\epsilon = 1/4$. Namely, $P(n, 1/4, 2) = 1$. If a graph G has a vertex which is adjacent to less than half of the other vertices, delete it. Continue deleting vertices until all vertices in the remaining induced subgraph G_1 are adjacent to at least half of the other vertices of G_1. Graph G_1 has diameter at most 2 by the discussion after Theorem 1.2. Let G_0 be the subgraph whose edges are those containing a deleted vertex. Then G_0 has at most $\frac{1}{2}\binom{n}{2} < n^2/4 = \epsilon n^2$ edges and therefore $P(n, 1/4, 2) = 1$.

2.2. Decomposing a graph into diameter 3 subgraphs

Studying $P(n, \epsilon, d)$ appears to be most interesting in the case $d = 3$. In this subsection, we prove Theorem 1.1(b), which establishes $P(n, \epsilon, 3) = \Theta(1/\epsilon^2)$ for $\epsilon \geqslant n^{-1/2}$. We begin with a few simple lemmas.

Lemma 2.2. *If G is a graph with n vertices and $m \geqslant 12n$ edges, then G has at least $\frac{m^3}{16n^2}$ paths of length three.*

Proof. Delete vertices of degree at most $\frac{m}{2n}$ one by one from G. The resulting induced subgraph G' has at least $m - n\frac{m}{2n} = m/2$ edges, and has minimum degree at least $\frac{m}{2n}$. For each edge $e = (u, v)$ of G', u and v each have at least $\frac{m}{2n}$ neighbours, so the number of paths of length three with middle edge e is at least $\left(\frac{m}{2n} - 1\right)\left(\frac{m}{2n} - 2\right) \geqslant \frac{m^2}{8n^2}$ as there are at least $\frac{m}{2n} - 1$ possible choices for the first vertex of the path, and, given the first three vertices of the path, at least $\frac{m}{2n} - 2$ remaining possible last vertices for the path. Counting over all $m/2$ possible middle edges, we obtain that the number of paths of length three in G' (and hence in G) is at least $\frac{m}{2}\frac{m^2}{8n^2} = \frac{m^3}{16n^2}$. $\qquad \square$

The next definition demonstrates how to construct a subgraph of diameter at most 3 from a graph and a pair of its vertices.

Definition 4. For a graph G and vertices v and w of distance at most d, let $G_d(v, w)$ be the induced subgraph of G consisting of all vertices of G that lie on a walk from v to w of length at most d.

Lemma 2.3. *The graph $G_d(v, w)$ has diameter at most d.*

Proof. Let a and b be vertices of $G_d(v, w)$. So a is on a walk from v to w of length at most d, and b is on a walk from v to w of length at most d. These two walks give rise to two walks from a to b such that the sum of the lengths of these two walks is at most $2d$. Hence, there is a path from a to b of length at most d. This shows that $G_d(v, w)$ has diameter at most d. $\qquad\square$

Lemma 2.4. *If a graph G has n vertices and $m \geqslant 12n$ edges, then it contains an induced subgraph H with at least $\frac{m^3}{32n^4}$ edges that has diameter at most 3.*

Proof. By Lemma 2.2, G has at least $\frac{m^3}{16n^2}$ paths of length three. By averaging, there is a pair u, v of vertices of G such that the number of paths of length three with terminal vertices u and v is at least $\frac{m^3}{16n^4}$. By Lemma 2.3, $G_3(u, v)$ has diameter at most 3 and in every path of length three from u to v, the middle edge is an edge of $G_3(u, v)$. Moreover, each edge in $G_3(u, v)$ is the middle edge of at most two paths from u to v, hence $G_3(u, v)$ has at least $\frac{m^3}{32n^4}$ edges. $\qquad\square$

We now prove a quantitative version of the upper bound on $P(n, \epsilon, 3)$ in Theorem 1.1(b).

Theorem 2.5. *Every graph G on n vertices can be edge-partitioned $E = E_0 \cup E_1 \cup \cdots \cup E_k$ such that $|E_0| \leqslant \epsilon n^2$, $k \leqslant 50\epsilon^{-2}$, and for $1 \leqslant i \leqslant k$, the diameter of E_i is at most 3.*

Proof. We can assume $\epsilon n^2 \geqslant 12n$, since otherwise $k \geqslant n$, and the result follows from the $d = 2$ case. We repeatedly use Lemma 2.4 to pull out subgraphs of diameter at most 3 until the remaining subgraph has at most ϵn^2 edges. The remaining at most ϵn^2 edges make up E_0. If the current graph has at least $m/2$ edges, then by the above lemma we can find a subgraph of diameter at most 3 with at least $\frac{(m/2)^3}{32n^4}$ edges. Therefore, after pulling out $s = (m - m/2)/\frac{(m/2)^3}{32n^4} = 128n^4/m^2$ such subgraphs of diameter at most 3, we are left with at most $m/2$ edges. Similarly, applying this process to a subgraph with at most $2^i \epsilon n^2$ edges we get a subgraph with at most $2^{i-1}\epsilon n^2$ edges, after pulling out at most $\frac{128n^4}{(2^i \epsilon n^2)^2} = 2^{7-2i}\epsilon^{-2}$ subgraphs of diameter 3. Summing over all $i \geqslant 1$, we obtain that altogether we pull out at most $\sum_{i=1}^{\infty} 2^{7-2i}\epsilon^{-2} = \frac{2^7}{3}\epsilon^{-2} < 50\epsilon^{-2}$ subgraphs. $\qquad\square$

Next we establish a lower bound on $P(n, \epsilon, 3)$, using the following two lemmas.

Lemma 2.6. *Almost surely, the subgraph of diameter at most 3 of the random bipartite graph $G(n, n, p)$ with $p = \frac{1}{4\sqrt{n}}$ with the maximum number of edges has $(1 + o(1))(2pn + p^3 n^2) = \left(\frac{33}{64} + o(1)\right)\sqrt{n}$ edges.*

Since almost surely the number of edges of $G(n, n, p)$, $p = \frac{1}{4\sqrt{n}}$, is concentrated around its expected value pn^2, we have the following corollary.

Corollary 2.7. *For all sufficiently large n, there is a bipartite graph on 2n vertices with at least $\frac{1}{5}n^{3/2}$ edges in which any diameter at most 3 subgraph has at most $\frac{4}{5}n^{1/2}$ edges.*

For a graph G, the *blow-up* $G(r)$ denotes the graph formed by replacing each vertex v_i of G by an independent set V_i of size r, where vertices $u \in V_i$ and $w \in V_j$ are adjacent in $G(r)$ if and only if v_i and v_j are adjacent in G.

Lemma 2.8. *If every subgraph of a graph G with diameter at most d has at most m edges, then every subgraph of G(r) with diameter at most d has at most $r^2 m$ edges.*

Proof. Let H be a subgraph of $G(r)$ of diameter at most d. Let H' be the induced subgraph of G, where v_i is a vertex of H' if there is a vertex of H in V_i. It is clear from the definition of $G(r)$ that the diameter of H' is at most the diameter of H. Thus H' also has diameter at most d and so it has at most m edges. Then H has at most $r^2 m$ edges, since for every edge (v_i, v_j) of H' there are at most r^2 edges of H in $V_i \times V_j$. $\square$

From Corollary 2.7 and Lemma 2.8, we quickly deduce a lower bound on $P(n, \epsilon, 3)$. Of course, we are assuming here that $\epsilon < 1/2$, as otherwise $\epsilon n^2 \geqslant \binom{n}{2}$ and $P(n, \epsilon, 3) = 0$, since we can let E_0 consist of all edges of the graph.

Theorem 2.9. *There is an absolute constant $c > 0$ such that for $\epsilon \geqslant n^{-1/2}$ we have $P(n, \epsilon, 3) \geqslant c\epsilon^{-2}$.*

Proof. Let $t = (40\epsilon)^{-2}$ and $r = \frac{n}{2t}$. We may suppose that ϵ is sufficiently small (as otherwise the theorem trivially holds since we may choose c so that $c\epsilon^{-2} \leqslant 1$) and so t is sufficiently large. Therefore, by Corollary 2.7, there is a bipartite graph G with $2t$ vertices and at least $\frac{1}{5}t^{3/2}$ edges such that every diameter 3 subgraph of G has at most $\frac{4}{5}t^{1/2}$ edges. The blow-up graph $G(r)$ has n vertices and at least $\frac{1}{5}t^{3/2}r^2 = 2\epsilon n^2$ edges, and Lemma 2.8 shows that any subgraph of $G(r)$ with diameter at most 3 has at most $\frac{4}{5}r^2 t^{1/2} = t^{-3/2}n^2/5 = 8(40)^2\epsilon^3 n^2$ edges. Thus $P(n, \epsilon, 3) \geqslant \frac{\epsilon n^2}{8(40)^2\epsilon^3 n^2} \geqslant \frac{1}{8(40)^2}\epsilon^{-2}$, which completes the proof. $\square$

We still have to prove Lemma 2.6, which is the main task of the rest of this subsection. We next include a simple characterization of bipartite graphs of diameter at most 3.

Proposition 2.10. *A bipartite graph G with at least three vertices has diameter at most 3 if and only if each pair of vertices in the same vertex class have a common neighbour.*

Proof. Let A and B be the vertex classes of bipartite G with $|A| \geqslant |B|$. If a pair of vertices in the same vertex class do not have a common neighbour, then the shortest path between them must be even, have length at least four, and hence G has diameter at least four.

Conversely, suppose each pair of vertices in the same vertex class have a common neighbour. If two vertices are in the same vertex class, then there is a path of length two

between them. If $a \in A$ and $b \in B$, then there is another vertex $a' \in A$, and hence a and a' have a neighbour b' in B. If $b' = b$, then there is a path of length one between a and b. Otherwise, b' and b have a common neighbour, so there is a path between a and b of length at most three. This shows that the distance between any pair of vertices of G is at most 3, *i.e.*, G has diameter at most 3. $\square$

As already discussed in Section 2.1, a bipartite graph with diameter less than 3 must be a complete bipartite graph. Hence a bipartite graph with at least three vertices has diameter exactly three if and only if it is not a complete bipartite graph and each pair of vertices in the same vertex class have a common neighbour.

Our goal for the rest of the subsection is to prove Lemma 2.6. We will assume that $p = \frac{1}{4\sqrt{n}}$, n is sufficiently large, and let A and B denote the vertex sets of size n of $G(n, n, p)$. We first need to collect several basic lemmas about the edge distribution in $G(n, n, p)$. The *neighbourhood* $N(v)$ of a vertex v in a graph G is the set of vertices adjacent to v.

Lemma 2.11. *$G(n, n, p)$ with $p = \frac{1}{4\sqrt{n}}$ almost surely has the following six properties.*

(a) *Every vertex has degree $(1 + o(1))pn$.*

(b) *Every pair of vertices have at most $\log n$ common neighbours.*

(c) *For every edge (a, b), there are $(1 + o(1))(2pn + p^3n^2)$ edges between $N(a)$ and $N(b)$.*

(d) *For all $a \in A$ and $b \in B$ non-adjacent, there are $(1 + o(1))p^3n^2$ edges between $N(a)$ and $N(b)$.*

(e) *For all $Y \subset B$ and $X \subset A$, there are at most $|X| + |Y|^2 \log n$ edges between X and Y.*

(f) *For all $A' \subset A$ and $B' \subset B$, there are at most $t = 6 \max(|A'||B'|p, (|A'| + |B'|)) \log n$ edges between A' and B'.*

Proof.   **(a)** The degree of each of the $2n$ vertices of $G(n, n, p)$ follows a binomial distribution. Chernoff's bound for the binomial distribution implies that almost surely all of the degrees are concentrated around their expected value, pn.

(b) The probability that a given pair of vertices in the same part have at least $\log n$ common neighbours is at most $\binom{n}{\log n}p^{2\log n} < n^{\log n}(4\sqrt{n})^{-2\log n} = n^{-4}$. There are $2\binom{n}{2} < n^2$ pairs of vertices in the same class of $G(n, n, p)$, so the probability that $G(n, n, p)$ has a pair of vertices with $\log n$ common neighbours is at most $n^{-4}n^2 = n^{-2}$.

(c) By (a), almost surely, the degree of every vertex in $G(n, n, p)$ is $(1 + o(1))pn$. If a and b are adjacent, given $|N(a)|$ and $|N(b)|$, the number of edges between $N(a) \setminus \{b\}$ and $N(b) \setminus \{a\}$ follows a binomial distribution. An application of Chernoff's bound for the binomial distribution implies that a.s. for each edge (a, b) the number of edges between $N(a)$ and $N(b)$ is

$$|N(a)| + |N(b)| - 1 + (1 + o(1))p(|N(a)| - 1)(|N(b)| - 1) = (1 + o(1))(2pn + p^3n^2).$$

(d) As for (c), an application of Chernoff's bound for the binomial distribution implies that almost surely, for each pair a, b of non-adjacent vertices in different vertex classes, the number of edges between $N(a)$ and $N(b)$ is $(1 + o(1))p|N(a)||N(b)| = (1 + o(1))p^3n^2$.

(e) Let $x_1, \ldots, x_k$ be the vertices of X with at least two neighbours in Y. Since every $d_Y(x_i) \geqslant 2$ and (by (b)) each pair of vertices in Y has at most $\log n$ common neighbours, we have

$$\frac{1}{2} \sum_i d_Y(x_i) \leqslant \sum_i \binom{d_Y(x_i)}{2} \leqslant \binom{|Y|}{2} \log n.$$

This implies that the total number of edges between X and Y is at most $|X| - k + \sum_i d_Y(x_i) \leqslant |X| + |Y|^2 \log n$.

(f) The result is trivial if A' or B' is empty, so we may assume they are non-empty. The number of pairs $A' \subset A$ and $B' \subset B$ of size $|A'| = a$ and $|B'| = b$ is $\binom{n}{a} \binom{n}{b}$. For fixed A' and B' of sizes a and b, respectively, the probability that there are at least t edges between them is at most $p^t \binom{ab}{t} \leqslant \left(\frac{abep}{t} \right)^t \leqslant 2^{-t} \leqslant n^{-6(a+b)}$. So the probability that there are such subsets A' and B' is at most

$$\sum_{a,b} \binom{n}{a} \binom{n}{b} n^{-6(a+b)} \leqslant \sum_{a,b} n^{a+b} n^{-6(a+b)} = \sum_{a,b} n^{-5(a+b)} \leqslant n^2 n^{-5} = n^{-3}. \qquad \square$$

Proof of Lemma 2.6. To see that there almost surely is a subgraph of diameter 3 of $G(n, n, p)$ with $(1 + o(1))(2pn + p^3 n^2)$ edges, let a and b be adjacent vertices in different vertex classes of $G(n, n, p)$, and consider the induced subgraph with vertex set $N(a) \cup N(b)$, which has diameter at most 3. By Lemma 2.11(c), this induced subgraph almost surely has $(1 + o(1))(2pn + p^3 n^2)$ edges. To prove Lemma 2.6, it thus suffices to show that *every* diameter 3 subgraph has at most $(1 + o(1))(2pn + p^3 n^2)$ edges.

Let H be a subgraph of the bipartite graph $G = G(n, n, p)$ of diameter at most 3, and let X and Y be its vertex sets with $|X| \geqslant |Y|$. In particular, according to Proposition 2.10, each pair of vertices of X have a common neighbour in Y, and each pair of vertices of Y have a common neighbour in X. We suppose for contradiction that H has more than $(1 + o(1))(2pn + p^3 n^2)$ edges. Adding extra edges to a graph on a given vertex set cannot increase the diameter of the graph, so we may suppose that H is the induced subgraph of G with vertex sets X and Y. In graph H, let $d_1 \geqslant d_2 \geqslant \cdots \geqslant d_{|Y|}$ be the degrees of the vertices of Y in decreasing order, and let v_i denote the vertex of degree d_i.

We first prove that H has few vertices.

Claim 1. *Almost surely, every diameter 3 subgraph H of $G(n, n, p)$ has at most $10n^{1/2} \log n$ vertices.*

Proof. Suppose for contradiction that H has at least $x = 10n^{1/2} \log n$ vertices. Since $|X| \geqslant |Y|$, we have $|X| \geqslant x/2 = 5n^{1/2} \log n$. Lemma 2.11(f) shows that almost surely there are at most $t = 6 \max(|X||Y|p, (|X| + |Y|) \log n) \leqslant 6|X| \max(p|X|, 2 \log n)$ edges between X and Y. Also, by Lemma 2.11(a), a.s. the maximum degree of G satisfies $\Delta = (1 + o(1))np$. Convexity of the function $f(y) = \binom{y}{2}$ yields

$$\sum_{i=1}^{|Y|} \binom{d_i}{2} \leqslant \frac{t}{\Delta} \binom{\Delta}{2} = (1 + o(1))npt/2 \leqslant 4np|X| \max(p|X|, 2 \log n),$$

which is an upper bound on the number of pairs of vertices of X that have a common neighbour in Y. We have $4np|X| \cdot p|X| < \binom{|X|}{2}$ and $4np|X| \cdot 2\log n < \binom{|X|}{2}$. Hence, there are fewer than $\binom{|X|}{2}$ pairs of vertices in X with a common neighbour in Y. So there is a pair of vertices in X with no common neighbour in Y, contradicting H has diameter at most 3 and completing the proof. $\qquad\square$

Lemma 2.11(f) together with the previous claim implies that a.s. any subgraph of $G(n, n, p)$ of diameter 3 with at least $2pn = \sqrt{n}/2$ edges has at least $\frac{1}{12}\frac{\sqrt{n}}{\log n}$ vertices and at most $10\sqrt{n}\log n$ vertices.

Claim 2. *Let $\epsilon = |X|^{-1/5}$. There is a vertex in Y that has at least $(1-\epsilon)|X|$ neighbours in X.*

Proof. Since every pair of vertices of X have a common neighbour in Y we have $\sum_{i=1}^{|Y|} \binom{d_i}{2} \geqslant \binom{|X|}{2}$, where $d_1 \geqslant d_2 \geqslant \cdots \geqslant d_{|Y|}$ are the degrees of vertices of Y in X. Suppose for contradiction that no vertex of Y has at least $(1-\epsilon)|X|$ neighbours in X. Let $r = |X|^{1/3}$. By Lemma 2.11(e), $\sum_{i=1}^{r} d_i \leqslant |X| + r^2 \log n$. In particular, convexity of the function $f(x) = \binom{x}{2}$ demonstrates that

$$\sum_{i=1}^{r} \binom{d_i}{2} \leqslant \binom{(1-\epsilon)|X|}{2} + \binom{\epsilon|X| + r^2 \log n}{2}$$

$$\leqslant \binom{(1-\epsilon)|X|}{2} + \epsilon^2 |X|^2 \leqslant \binom{|X|}{2} - \epsilon|X|^2/2.$$

Since H and hence also X has at most $10\sqrt{n}\log n$ vertices, we have that $|X|^2 p \leqslant \frac{5}{2}|X|\log n$. Thus, by Lemma 2.11(f), there are at most $15|X|\log n$ edges from Y to X. This implies that $\sum_{i>r} d_i \leqslant 15|X|\log n$ and also $d_i \leqslant d_r \leqslant (15|X|\log n)/r$ for all $i > r$. Under these constraints, we have by convexity of the function $f(x) = \binom{x}{2}$ that

$$\sum_{i>r} \binom{d_i}{2} \leqslant r\binom{15|X|\log n/r}{2} < \frac{120}{r}|X|^2 \log^2 n = 120|X|^{5/3}\log^2 n \ll \frac{1}{2}|X|^{9/5} = \frac{1}{2}\epsilon|X|^2.$$

This together with the above estimate shows that $\sum_{i=1}^{|Y|} \binom{d_i}{2} < \binom{|X|}{2}$, a contradiction. $\qquad\square$

Take ϵ as in Claim 2. Since there is a vertex in Y with at least $(1-\epsilon)|X|$ neighbours in X and every vertex has degree $(1+o(1))pn$, then $|X| \leqslant (1+o(1))pn/(1-\epsilon) = (1+o(1))pn$.

We next show that Y is also quite large if H has at least $2pn$ edges. By Claim 2, there is a vertex $v \in Y$ adjacent to at least $(1-\epsilon)|X|$ elements of X. By Lemma 2.11(b), every other vertex in Y besides v has at most $\log n$ neighbours in $N(v)$. Hence, there are at most $|X| + |Y|\log n$ edges between $N(v)$ and Y. There are at most $\epsilon|X|$ vertices in $X \setminus N(v)$, so there are at most $6\max(\epsilon|X||Y|p, (\epsilon|X| + |Y|)\log n)$ edges between $X \setminus N(v)$ and Y. Hence the number of edges of H is at most

$$|X| + |Y|\log n + 6\max(\epsilon|X||Y|p, (\epsilon|X| + |Y|)\log n) \leqslant (1+o(1))pn + 7|Y|\log n,$$

where we use $|X| \leqslant (1 + o(1))pn$. If $|Y| \leqslant \frac{1}{30}\frac{\sqrt{n}}{\log n}$, we get that there are fewer than $2pn$ edges in H, a contradiction. To summarize, we have the following inequalities:

$$\frac{\sqrt{n}}{30 \log n} \leqslant |Y| \leqslant |X| \leqslant (1 + o(1))pn.$$

Now that we have established that X and Y are of similar size, the proof of Claim 2 with X and Y switched also gives us the following claim. The only estimate in the proof that needs to be checked is that $|X|^2(\log n)^2/r \ll \epsilon |Y|^2$, and since $|X|$ and $|Y|$ are both of the form $n^{1/2+o(1)}$, $r = |Y|^{1/3}$ and $\epsilon = |Y|^{-1/5}$, this clearly holds.

Claim 3. *Let $\epsilon = |Y|^{-1/5}$. There is a vertex in X that has at least $(1 - \epsilon)|Y|$ neighbours in Y.*

We now complete the proof of Lemma 2.6. Let y be a vertex in Y with at least $(1 - \epsilon)|X|$ neighbours in X and let x be a vertex in X with at least $(1 - \epsilon)|Y|$ neighbours in Y, where $\epsilon = |Y|^{-1/5}$. Such vertices x and y exist by Claims 2 and 3, since $|Y| \leqslant |X|$. Let X_1 be the set of neighbours of y in X, and $X_2 = X \setminus X_1$. Let Y_1 denote the set of neighbours of x in Y, and $Y_2 = Y \setminus Y_1$. By Lemma 2.11(c), if x and y are adjacent and Lemma 2.11(a) and (d) if x and y are not adjacent, there are at most $(1 + o(1))(2pn + p^3n^2)$ edges between $X_1 \cup \{x\}$ and $Y_1 \cup \{y\}$. Since X_1 consists of neighbours of y, by Lemma 2.11(b), each vertex in $Y_2 \setminus \{y\}$ has at most $\log n$ neighbours in X_1. Similarly, each vertex in $X_2 \setminus \{x\}$ has at most $\log n$ neighbours in Y_1. Lemma 2.11(f) implies that the number of edges between X_2 and Y_2 is at most

$$6 \max(|X_2||Y_2|p, (|X_2| + |Y_2|)\log n) \leqslant 6 \max(\epsilon|X|\epsilon|Y|p, (\epsilon|X| + \epsilon|Y|)\log n)$$
$$< 20\epsilon|X|\log n = o(n^{1/2}).$$

Putting these inequalities altogether, the number of edges between X and Y, and hence the number of edges of H, is at most

$$(1 + o(1))(2pn + p^3n^2) + |X_2|\log n + |Y_2|\log n + o(n^{1/2}) = (1 + o(1))(2pn + p^3n^2),$$

where we use $|X_2| \leqslant \epsilon|X| = o(n^{1/2})$ and $|Y_2| \leqslant \epsilon|Y| = o(n^{1/2})$, which completes the proof. $\square$

2.3. Decomposing a graph into diameter 4 subgraphs

In this subsection, we prove the last claim of Theorem 1.1, that $P(n, \epsilon, d) = \Theta(1/\epsilon)$ for $d \geqslant 4$ and $\epsilon \geqslant 1/n$.

Definition 5. For a vertex v and graph G, let $N_r(v)$ be those vertices of G that are within distance at most r from vertex v and let $G_r(v)$ denote the induced subgraph of G with vertex set $N_r(v)$.

The graph $G_r(v)$ of course has radius at most r and hence diameter at most $2r$. Note that $G_r(v) = G_{2r}(v, v)$ (defined in the previous section), as any vertex at distance at most r

from v is contained in a walk from v to v of length at most $2r$, and any walk from v to v of length at most $2r$ contains only vertices of distance at most r from v.

To bound $P(n, \epsilon, 4)$ from above we use the following lemma, which is tight apart from the constant factor, as demonstrated by a disjoint union of cliques of equal size (see the proof of Lemma 2.14 below).

Lemma 2.12. *If a graph G has n vertices and at least $m \geqslant 4n$ edges, then it has a subgraph with diameter at most 4 and at least $\frac{m^2}{8n^2}$ edges.*

Proof. Delete vertices one by one of degree at most $\frac{m}{2n}$. The resulting induced subgraph G' has at least $m - n\frac{m}{2n} = m/2$ edges and minimum degree at least $\frac{m}{2n}$. For any vertex v of G', $G'_2(v)$ has diameter at most 4 and at least $(\frac{m}{2n})^2/2 = \frac{m^2}{8n^2}$ edges as v and its neighbours have degree at least $\frac{m}{2n}$. $\qquad\square$

We now prove a quantitative version of the upper bound on $P(n, \epsilon, 4)$ in Theorem 1.1(c).

Theorem 2.13. *Every graph G on n vertices can be edge-partitioned $E = E_0 \cup E_1 \cup \cdots \cup E_\ell$ such that $|E_0| \leqslant \epsilon n^2$, $\ell \leqslant 16\epsilon^{-1}$, and for $1 \leqslant i \leqslant \ell$, the diameter of E_i is at most 4.*

Proof. We may assume $\epsilon \geqslant 8n^{-1}$, as in the case $\epsilon < 8n^{-1}$ we can use the bound $P(n, \epsilon, 4) \leqslant P(n, 0, 2) \leqslant n$ from the beginning of Section 2.1. We repeatedly use Lemma 2.12 to pull out subgraphs of diameter at most 4 until the remaining subgraph has at most ϵn^2 edges. The remaining at most ϵn^2 edges make up E_0. If the current graph has at least $m/2$ edges, then by the above lemma we can pull out a subgraph of diameter at most 4 with at least $(m/2)^2/8n^2$ edges. Therefore, after pulling out $s = (m - m/2)/\frac{(m/2)^2}{8n^2} = 16n^2/m$ subgraphs of diameter at most 4 from our graph, we are left with at most $m/2$ edges. Similarly, applying this process to a graph with at most $2^i\epsilon n^2$ edges we get a subgraph with at most $2^{i-1}\epsilon n^2$ edges, after we pull out at most $\frac{16n^2}{2^i\epsilon n^2} = 2^{4-i}\epsilon^{-1}$ subgraphs of diameter 4. Summing over all $i \geqslant 1$, the total number ℓ of subgraphs of diameter at most 4 we pull out is at most $\sum_{i=1}^{\infty} 2^{4-i}\epsilon^{-1} = 16\epsilon^{-1}$. $\qquad\square$

The next lemma shows that Theorem 2.13 is tight apart from a constant factor.

Lemma 2.14. *If $\frac{1}{4n} \leqslant \epsilon \leqslant \frac{1}{16}$, then $P(n, \epsilon, d) \geqslant \frac{1}{16\epsilon}$.*

Proof. Let $t = \frac{1}{8\epsilon}$ (note that $t \leqslant n/2$) and let G be a graph consisting of n vertices partitioned into t disjoint cliques each of size n/t. The graph G has $t\binom{n/t}{2}$ edges. Any connected subgraph of G has at most $\binom{n/t}{2}$ edges. Hence, any partition $E = E_0 \cup E_1 \cup \cdots \cup E_\ell$ such that $|E_0| \leqslant \epsilon n^2 \leqslant \frac{t}{2}\binom{n/t}{2}$ and each E_i is connected for $1 \leqslant i \leqslant \ell$ must have $\ell \geqslant t/2 = \frac{1}{16\epsilon}$. $\qquad\square$

3. Covering graphs of large minimum degree

In this section, we prove results on the minimum number of low-diameter subgraphs needed to cover *all the edges* of a graph of large minimum degree. We consider the cases of diameter 3, 4, 5, 6 in separate subsections.

3.1. Covering graphs by diameter 3 subgraphs

First we show, using a simple sampling argument, that the edges of every graph with n vertices and minimum degree linear in n can be covered by $O(\log n)$ subgraphs of diameter at most 3.

Theorem 3.1. *Let $G = (V, E)$ be a graph on n vertices with minimum degree at least ϵn. Then there is a covering $E = E_1 \cup \cdots \cup E_\ell$ of the edge set of G such that $\ell = 2\epsilon^{-2} \ln n$ and for $1 \leqslant i \leqslant \ell$, E_i has diameter at most 3.*

Proof. Pick ℓ pairs (v_i, w_i) of not necessarily distinct vertices uniformly at random with repetition. If there is a path of length at most 3 between v_i and w_i, let $G_3(v_i, w_i)$ be the induced subgraph of G as in Definition 4 and let E_i be the edge set of $G_3(v_i, w_i)$. By Lemma 2.3, $G_3(v_i, w_i)$ has diameter at most 3. Let (v, w) be an edge of G. If $v_i \in \{v\} \cup N(v)$ and $w_i \in \{w\} \cup N(w)$, then $G_3(v_i, w_i)$ contains (v, w) as there is a walk from v_i to w_i of length at most 3 containing (v, w). So the probability that a given edge (v, w) of G is in $G_3(v_i, w_i)$ is at least $\frac{|N(v)|}{n} \frac{|N(w)|}{n} \geqslant \epsilon^2$. Since we are picking $\ell = 2\epsilon^{-2} \ln n$ pairs of vertices uniformly at random, the probability that (v, w) is in none of these subgraphs is at most $(1 - \epsilon^2)^\ell < e^{-2 \ln n} = n^{-2}$. Summing over all edges of G, the expected number of edges of G that are not in any of the E_i is at most $\binom{n}{2} n^{-2} < 1/2$. Hence, there is a choice of $E_1, \ldots, E_\ell$, each having diameter at most 3, that together cover all edges of G. This completes the proof. $\square$

3.2. Covering graphs by diameter 4 subgraphs

The family of all subsets of $[n] = \{1, \ldots, n\}$ of size k is denoted by $\binom{[n]}{k}$. The *Kneser graph* $\mathrm{KG}(n, k)$ has vertex set $\binom{[n]}{k}$, where two sets of size k are adjacent if they are disjoint. A famous theorem of Lovász [10], who proved Kneser's conjecture using topological methods, states that the chromatic number of $\mathrm{KG}(n, k)$ is $n - 2k + 2$ for $n \geqslant 2k \geqslant 2$. We use this property of Kneser graphs to construct a graph demonstrating that the bound in Theorem 3.1 is tight up to a constant factor. This will complete the proof of Theorem 1.2(a).

Theorem 3.2. *For every sufficiently large N, there is a graph G on N vertices with minimum degree at least $2^{-8} N$ whose edges cannot be covered by $\frac{1}{2} \log_2 N$ subgraphs of diameter at most 4.*

We establish Theorem 3.2 using the following lemma.

Lemma 3.3. *For $k \geqslant 1$, let $a_k = 4\binom{4k}{k}$. There is a graph F_k on a_k vertices with minimum degree $a_k/16$ such that any covering of the edges of F_k by subgraphs of diameter at most 4 uses at least $2k + 2$ subgraphs.*

To deduce Theorem 3.2 from Lemma 3.3, we let k be the largest positive integer such that $a_k \leqslant N$. If a_k is not exactly N, we can duplicate some vertices of F_k if necessary to get the desired graph G with N vertices. Indeed, as $N < a_{k+1} \leqslant 10a_k$ and $a_k = 4\binom{4k}{k} \leqslant 2^{4k}$, we have that G has minimum degree at least $a_k/16 \geqslant 2^{-8}N$ and the edges of G cannot be covered by fewer than $2k + 2 > \frac{1}{2}\log_2 N$ subgraphs of diameter at most 4. It thus suffices to prove Lemma 3.3.

The *incidence graph* $\mathrm{IG}(n,k)$ is a bipartite graph with first vertex class $\binom{[n]}{k}$ and second vertex class $[n]$, where $i \in [n]$ is adjacent to $S \in \binom{[n]}{k}$ if $i \in S$. Every vertex in the first vertex class has k neighbours, and every vertex in the second vertex class has $\binom{n-1}{k-1} = \frac{k}{n}\binom{n}{k}$ neighbours. Two vertices $S_1, S_2 \in \binom{[n]}{k}$ have a common neighbour in $\mathrm{IG}(n,k)$ if and only if they have non-empty intersection. So any colouring of $\binom{[n]}{k}$ such that any pair S_1, S_2 of the same colour has a neighbour in common in $\mathrm{IG}(n,k)$ gives a proper vertex colouring of $\mathrm{KG}(n,k)$. Since $\mathrm{IG}(n,k)$ is bipartite, the number of colours in any colouring of $\binom{[n]}{k}$ in which any pair S_1, S_2 of the same colour has distance less than 4 in $\mathrm{IG}(n,k)$ is at least the chromatic number of $\mathrm{KG}(n,k)$, which is $n - 2k + 2$.

Let $\mathrm{H}(n,k,t)$ denote the graph with first vertex class $\binom{[n]}{k}$ and second vertex class $[nt]$, where the bipartite graph between $\binom{[n]}{k}$ and $\{n(j-1)+1,\ldots,nj\}$ makes a copy of $IG(n,k)$ for $1 \leqslant j \leqslant t$. By construction, any colouring of $\binom{[n]}{k}$ in which any pair S_1, S_2 of the same colour has distance less than 4 in $\mathrm{H}(n,k,t)$ uses at least $n - 2k + 2$ colours. Let $t = \frac{1}{4k}\binom{4k}{k}$ and $H_k = H(4k,k,t)$. The number of vertices of H_k is $a_k/2$, and every vertex has degree $\frac{1}{4}\binom{4k}{k} = a_k/16$. We have established the following lemma.

Lemma 3.4. *The bipartite graph H_k is $a_k/16$-regular with $a_k/2$ vertices, and every colouring of the first vertex class of H_k such that every pair of vertices of the same colour has distance less than 4 uses at least $2k + 2$ colours.*

Let F_k be the graph consisting of two disjoint copies H_k^1, H_k^2 of H_k with an edge between the two copies S^1 and S^2 of S for each vertex $S \in \binom{[n]}{k}$ in the first vertex class of H_k. Notice that F_k has $2|H_k| = a_k$ vertices and has minimum degree $a_k/16$. To complete the proof of Lemma 3.3 and hence of Theorem 3.2, it suffices to show that in any covering $E(F_k) = E_1 \cup \cdots \cup E_\ell$ in which each E_i has diameter at most 4, the number ℓ of subgraphs used is at least $2k + 2$. Given such an edge covering of F_k, define a colouring $\chi : \binom{[n]}{k} \longrightarrow [\ell]$ as follows. Let $\chi(S) = i$ if i is the smallest positive integer such that the edge between the two copies of S in F_k is in E_i.

The key observation is that if $\chi(S) = \chi(T) = i$ and the distance between S and T is at least four in H_k, then the distance between S^1 and T^2 is at least 5 in F_k, which contradicts that E_i has diameter at most 4. Indeed, in any path from S^1 to T^2, one of the edges between the two copies of H_k must be used, as well as at least four edges inside copies

of H_k. Thus this colouring satisfies the conditions of Lemma 3.4 and therefore χ uses at least $\ell \geqslant 2k + 2$ colours. This completes the proof of Lemma 3.3 and of Theorem 3.2. $\square$

3.3. Covering graphs by diameter 5 subgraphs

We next show how to cover all the edges of a graph of large minimum degree by a small number of subgraphs each of diameter at most 5. Recall from Section 2.2 that $G_d(v, w)$ is the induced subgraph of G consisting of all vertices on a walk from v to w of length at most d. Lemma 2.3 states that $G_d(v, w)$ has diameter at most d. As in Section 2.3, $N_r(v)$ denotes all the vertices of G within distance at most r from v and $G_r(v)$ is the induced subgraph of G with vertex set $N_r(v)$.

Lemma 3.5. *We have $Q(n, \epsilon, 5) < \epsilon^{-2}$. That is, every graph G with n vertices and minimum degree at least ϵn has an edge covering $E = E_1 \cup \cdots \cup E_\ell$ with each E_i having diameter at most 5 and $\ell < \epsilon^{-2}$.*

Proof. Let $\{v_1, \ldots, v_t\}$ be a maximal set of vertices in G of distance more than 2 apart from each other. By definition, every vertex of G has distance at most 2 from one of these vertices. It follows that every edge of G has both its vertices in some $N_2(v_i)$ or one vertex in a set $N_2(v_i)$ and the other vertex in a different set $N_2(v_j)$. Note that in the latter case the edge lies in a walk of length at most 5 from v_i to v_j. For each pair v_i, v_j of distance at most 5, we will use the subgraph $G_5(v_i, v_j)$. Also, we will use the subgraph $G_2(v_i)$ for each i. The number ℓ of subgraphs we use is at most $t + \binom{t}{2} \leqslant t^2$ and every edge is in at least one of these diameter at most 5 subgraphs. Since $N_1(v_1), \ldots, N_1(v_t)$ are disjoint sets of vertices, each of size at least $1 + \epsilon n$, then $t < \epsilon^{-1}$ and hence $\ell < \epsilon^{-2}$. $\square$

We now present a lower bound for $Q(n, \epsilon, 5)$.

Theorem 3.6. *There are positive constants c and c' such that $Q(n, \epsilon, 5) > c\epsilon^{-2}$ for $\epsilon > c'(\log n)^{-1/3}$.*

Let k be the minimum positive integer such that $d := n/a_k \leqslant 2^{-4}\epsilon^{-1}$ with $a_k = 4\binom{4k}{k}$. The assumption $\epsilon > c'(\log n)^{-1/3}$ in Theorem 3.6 and the fact that a_k grows exponentially in k implies that $k \geqslant d^3$ for some appropriately chosen constant c'. Since $a_k \leqslant 10a_{k-1}$, we have $d \geqslant 10^{-1} \cdot 2^{-4}\epsilon^{-1}$. We will construct a graph G on n vertices with minimum degree at least ϵn such that any covering of the edges of G by subgraphs of diameter at most 5 uses at least $d^2 \geqslant 2^{-15}\epsilon^{-2}$ subgraphs, which implies Theorem 3.6.

Let H_k be the bipartite graph as defined before Lemma 3.4. By Lemma 3.4, H_k is $a_k/16$-regular with $a_k/2$ vertices, and every colouring of the first vertex class of H_k such that every pair of vertices of the same colour has distance less than 4 uses at least $2k + 2$ colours. Let F be the graph consisting of d disjoint copies of H_k with no edges between them. The graph F is bipartite, and we call the union of the d copies of the first vertex class of H_k *the first vertex class of F*, and the remaining vertices *the second vertex class of F*. Let G be the graph consisting of two disjoint copies F_1, F_2 of F, with a certain

matching between the first vertex class of F_1 and the first vertex class of F_2, which we define in the next paragraph.

Recall that the first vertex class of H_k is the vertex set of the Kneser graph $\mathrm{KG}(4k, k)$, and a pair of vertices in the first vertex class of H_k has distance less than 4 if and only if they are not adjacent in $\mathrm{KG}(4k, k)$. Let $\binom{[4k]}{k} = U_1 \cup \cdots \cup U_d$ be a partition of the vertex set of the Kneser graph $\mathrm{KG}(4k, k)$ into d sets such that for $1 \leqslant i \leqslant d$ the induced subgraph of $\mathrm{KG}(4k, k)$ with vertex set U_i has chromatic number at least $\lfloor 2k/d \rfloor \geqslant 2d^2$. Such a partition exists since for *any* partition $\chi(\mathrm{KG}(4k, k)) = p_1 + \cdots + p_d$ of the chromatic number of a graph $\mathrm{KG}(4k, k)$ into non-negative integers, there is a partition $U_1 \cup \cdots \cup U_d$ of the vertex set into subsets such that the induced subgraph of $\mathrm{KG}(4k, k)$ with vertex set U_i has chromatic number p_i. Indeed, we can take U_i to be the union of p_i colour classes in a proper colouring of $\mathrm{KG}(4k, k)$ with $\chi(\mathrm{KG}(4k, k))$ colours. For $j \in \{1, 2\}$, $1 \leqslant i \leqslant d$, and $S \subset [4k]$ with $|S| = k$, let $S_{i,j}$ be the copy of vertex S in the ith copy of H_k in F_j. Suppose that $S \in U_b$. Then the matching between the first vertex class of F_1 and the first vertex class of F_2 is defined by $S_{i,1}$ is adjacent to $S_{i+b,2}$, where $i + b$ is taken modulo d. We denote by $A_{i,j}$ and $B_{i,j}$ the first vertex class and the second vertex class, respectively, of the ith copy of H_k in F_j.

By definition, graph G has $2d \cdot a_k/2 = da_k = n$ vertices and minimum degree at least $a_k/16 \geqslant \epsilon n$. Hence, Theorem 3.6 follows from the next lemma.

Lemma 3.7. *Any edge covering of G by diameter at most 5 subgraphs uses at least d^2 subgraphs.*

Before proving Lemma 3.7, we first establish some properties of distances between vertices in G.

Claim 4. *If $v \in A_{i,j}$ and $v' \in A_{i',j}$ with $i \neq i'$, then v and v' have distance at least 4 in G.*

Let $v \in A_{i,j}$ and $v' \in A_{i',j}$ be the closest pair of vertices in these two sets. To verify the claim, let $v = v_1, v_2, \ldots, v_t = v'$ be a shortest path from v to v'. The vertex v_2, being a neighbour of v, must be in $B_{i,j}$ or in the first vertex class of F_{3-j}. If $v_2 \in B_{i,j}$ then $v_3 \in A_{i,j}$, and we could instead start from v_3 and get to v' in a shorter path, a contradiction. Therefore, v_2 is in the first vertex class of F_{3-j}. Similarly, we must have that v_{t-1} is in the first vertex class of F_{3-j}. We have $v_2 \neq v_{t-1}$ since the edge between v and v_2 is one of the edges of the matching, and the edge between v_{t-1} and v' is one of the edges of the matching, which would otherwise imply that v_2 is in two edges of a matching, a contradiction. We have $v_3 \neq v$, as otherwise we would get a shorter path from v to v'. This implies that v_3, being a neighbour of v_2, lies in the second vertex class of F_{3-j}. Hence $t - 1 \geqslant 4$ and the distance between v and v' is at least 4.

Claim 5. *If $v \in B_{i,j}$ and $w \in B_{i',j}$ with $i \neq i'$, then v and w have distance at least 6 in G.*

Indeed, consider a shortest path from v to w. The second vertex of this path is in $A_{i,j}$ as all the neighbours of v lie in $A_{i,j}$, and the second-to-last vertex of this path is in $A_{i',j}$ as

it is adjacent to w. By Claim 4, any vertex in $A_{i,j}$ has distance at least 4 from any vertex in $A_{i',j}$. Hence, v and w have distance at least 6.

Proof of Lemma 3.7. Suppose for contradiction that there are $r < d^2$ subgraphs $G_1, \ldots, G_r$ of G, each of diameter at most 5, which cover the edges of G. It follows from Claim 5 that any diameter at most 5 subgraph of G cannot contain a vertex in $B_{i,j}$ and also a vertex in $B_{i',j}$ with $i \neq i'$. Hence, for each h, $1 \leqslant h \leqslant r$, there is at most one pair (i, i') such that G_h contains both a vertex of $B_{i,1}$ and a vertex of $B_{i',2}$. Since $r < d^2$, the pigeonhole principle implies that there is a pair (i, i') such that no G_h contains a vertex of $B_{i,1}$ together with a vertex of $B_{i',2}$. Fix such a pair (i, i'). For each h, $1 \leqslant h \leqslant r$, let V_h denote the collection of all sets $S \in \binom{[4k]}{k}$ such that vertices $S_{i,1}$ and $S_{i',2}$ form an edge of the matching that belongs to G_h. By definition of such an edge, the set S is in $U_{i'-i}$, where the subscript is taken modulo d. Recall that the induced subgraph of KG$(4k, k)$ with vertex set $U_{i'-i}$ has chromatic number at least $2d^2$. We use the following claim.

Claim 6. *If S, S' are vertices in the first vertex class of H_k, then the distance between $S_{i,j}$ and $S'_{i,j}$ in G is the distance between S and S' in H_k.*

Indeed, $S_{i,j}$ and $S'_{i,j}$ belong to a copy of H_k in G, so their distance in G is at most the distance of S and S' in H_k. In the other direction, it is easy to see that any path in G from $S_{i,j}$ to $S'_{i,j}$ can be projected onto a path which is not longer from S to S' in H_k, which verifies Claim 6.

The next claim completes the proof of Lemma 3.7. Indeed, since $G_1, \ldots, G_r$ cover the edges of G, we must have $U_{i'-i} = V_1 \cup \cdots \cup V_r$. Claim 7 implies that each V_h forms an independent set in KG$(4k, k)$ and hence $r \geqslant 2d^2$.

Claim 7. *Each pair of vertices in V_h have distance less than 4 in H_k, i.e., V_h forms an independent set in KG$(4k, k)$.*

To prove Claim 7, suppose for contradiction that $S, S' \in V_h$ have distance at least 4 in H_k. Without loss of generality, suppose G_h contains no vertex in $B_{i,1}$ (the other case in which G_h contains no vertex in $B_{i',2}$ can be treated similarly). We claim that the distance between $S_{i,1}$ and $S'_{i,1}$ in G_h is at least 6. Indeed, the only vertex adjacent to $S_{i,1}$ in G_h is $S_{i',2}$ and the only vertex adjacent to $S'_{i,1}$ in G_h is $S'_{i',2}$. Since S and S' have distance at least 4 in H_k, by Claim 6, $S_{i',2}$ and $S'_{i',2}$ have distance at least 4 in G and hence also in G_h. Therefore, $S_{i,1}$ and $S'_{i,1}$ have distance at least 6 in G_h, contradicting the fact that G_h has diameter at most 5. $\qquad\square$

3.4. Covering graphs by diameter 6 subgraphs

We next show that $Q(n, \epsilon, d) = \Theta(\epsilon^{-1})$ for $d \geqslant 6$ and $\epsilon \geqslant 1/n$. The lower bound follows by considering a disjoint union of cliques, each with at least $\epsilon n + 1$ vertices. The upper bound also has a simple proof.

Lemma 3.8. *Every graph G with n vertices and minimum degree at least ϵn has an edge covering $E = E_1 \cup \cdots \cup E_\ell$, with each E_i having diameter at most 6 and $\ell < \epsilon^{-1}$.*

Proof. Let $\{v_1, \ldots, v_\ell\}$ be a maximal set of vertices in G of distance more than 2 apart from each other. Then every vertex of G has distance at most 2 from one of these vertices and therefore every edge of G has both of its endpoints within distance at most 3 from some v_i. This implies that the ℓ subgraphs $G_3(v_1), \ldots, G_3(v_\ell)$ cover all the edges of G and each of them has diameter at most 6. Since $N_1(v_1), \ldots, N_1(v_\ell)$ are disjoint sets of vertices of size at least $1 + \epsilon n$, then $\ell < \epsilon^{-1}$. $\qquad \square$

4. Decomposing hypergraphs into low-diameter subgraphs

We start this section by showing how to decompose the edge set of a k-uniform hypergraph on n vertices, apart from at most ϵn^k edges, into a small number of subhypergraphs of diameter at most 3. This will establish an upper bound on $P_k(n, \epsilon, 3)$. We then present two constructions giving lower bounds on $P_k(n, \epsilon, d)$.

Let H^k denote the following k-uniform hypergraph on $2k$ vertices with $k + 2$ edges. Its vertex set consist of two disjoint k-sets $V = \{v_i\}_{i=1}^{k}$ and $W = \{w_i\}_{i=1}^{k}$. The sets V and W are edges of H^k. For $1 \leqslant i \leqslant k$, vertex w_i together with all vertices $v_j, j \neq i$ also form an edge of H^k.

Let G be a k-uniform hypergraph and let $e = \{v_1, \ldots, v_k\}$ be a fixed edge of G. Consider all the vertices of G which are contained in some edge of G which intersects e in at least $k - 1$ vertices. Let $G(e)$ be the subhypergraph of G induced by this set. Since the intersection of e with itself has size k, by definition, all the vertices of e are in $G(e)$. Moreover e is an edge of $G(e)$ as well.

Lemma 4.1. *For each edge e of a k-uniform hypergraph G, the diameter of $G(e)$ is at most 3.*

Proof. Suppose a, b are distinct vertices of $G(e)$. Then there are two indices $1 \leqslant i, j \leqslant k$ such that $\{a\} \cup (e \setminus \{v_i\})$ and $\{b\} \cup (e \setminus \{v_j\})$ are both edges of $G(e)$. If $i = j$, then the sequence a, followed by all elements of $e \setminus v_i$, followed by b is a path of length 2. If $i \neq j$, and $a = v_i$ or $b = v_j$, then a and b are in an edge of $G(e)$. If $i \neq j$ and neither $a = v_i$ nor $b = v_j$, then the sequence with first element a, followed by v_j, followed by all vertices of $e \setminus \{v_i, v_j\}$, followed by v_i and finally by b is a path of length 3. In any case, there is a path of length at most 3 with endpoints a and b, and hence the diameter of $G(e)$ is at most 3. $\qquad \square$

The number of edges of $G(e)$ is at least the number of copies of H^k in G for which the image of set V is fixed as e. Indeed, if two disjoint edges e and f (together with some other edges of G) form a copy of H^k with f being the image of W, then each vertex in f is in $G(e)$, and so f is an edge of $G(e)$.

The *edge density* of a k-uniform hypergraph is the fraction of subsets of vertices of size k which are edges. Let $K(t; k)$ denote the complete k-partite k-uniform hypergraph with

parts of size t, whose edges are all the k-sets which intersect every part in one vertex. This hypergraph has kt vertices and t^k edges. The following well-known lemma is proved by a straightforward counting argument and induction on the uniformity k (see [7]).

Lemma 4.2. *Fix positive integers k and t. If G is a k-uniform hypergraph with n vertices and edge density ϵ with $\epsilon \gg n^{-t^{1-k}}$, then G contains $\Omega(\epsilon^{t^k} n^{kt})$ labelled copies of $K(t;k)$.*

We next deduce the following lemma.

Lemma 4.3. *For each positive integer k, there exists $c_k > 0$ such that the following holds. If G is a k-uniform hypergraph with n vertices and edge density ϵ with $\epsilon \gg n^{-t^{1-k}}$, then G contains a subhypergraph with diameter at most 3 and at least $c_k \epsilon^{2^k-1} n^k$ edges.*

Proof. Since H^k is a subhypergraph of $K(2;k)$, Lemma 4.2 implies that G contains $\Omega(\epsilon^{2^k} n^{2k})$ labelled copies of $K(2;k)$ and hence of H^k. Therefore, there is an edge e for which $G(e)$ contains at least $\Omega\big(\epsilon^{2^k} n^{2k}/\epsilon\binom{n}{k} k!\big) = \Omega\big(\epsilon^{2^k-1} n^k\big)$ edges. By Lemma 4.1, this subhypergraph has diameter at most 3. $\square$

We next obtain Theorem 1.3(a) by using the above fact to pull out from G subhypergraphs of diameter 3 with many edges until there are at most ϵn^k edges left.

Theorem 4.4. *We have $P_k(n, \epsilon, 3) = O(\epsilon^{2-2^k})$ for $\epsilon \gg n^{-2^{1-k}}$.*

Proof. We repeatedly use Lemma 4.3 to pull out subhypergraphs of diameter at most 3 until the remaining subhypergraph has at most ϵn^k edges. The remaining at most ϵn^k edges make up E_0. If the current hypergraph has at least $m/2$ edges, then its edge density is at least $\frac{m/2}{\binom{n}{k}} \geqslant mn^{-k}$, and by Lemma 4.3 we can pull out a subhypergraph of diameter at most 3 with at least $c_k(mn^{-k})^{2^k-1} n^k$ edges. Thus, after removing $s = m/\big(c_k(mn^{-k})^{2^k-1} n^k\big) = c_k^{-1}(mn^{-k})^{2-2^k}$ subhypergraphs of diameter at most 3 from our hypergraph, we are left with at most $m/2$ edges. Similarly, applying this process to a hypergraph with at most $2^i \epsilon n^k$ edges we get a subhypergraph with at most $2^{i-1} \epsilon n^k$ edges, after we pull out at most $c_k^{-1}(2^i \epsilon)^{2-2^k}$ subhypergraphs of diameter 3. Summing over all $i \geqslant 1$, the total number of subhypergraphs of diameter at most 3 we pull out is at most $\sum_{i=1}^{\infty} c_k^{-1}(2^i \epsilon)^{2-2^k} = O(\epsilon^{2-2^k})$, which gives the desired upper bound on $P_k(n, \epsilon, 3)$. $\square$

The next theorem, which verifies Theorem 1.3(b), gives a lower bound on $P_k(n, \epsilon, 3)$ that we conjecture is tight apart from the constant factor.

Theorem 4.5. *We have $P_k(n, \epsilon, 3) \geqslant c_k \epsilon^{-k}$ for $n^{-1/2} \leqslant \epsilon \leqslant C_k$, where c_k and C_k are positive constants depending only on k.*

We prove this theorem by showing that there is a dense k-uniform hypergraph with no large subhypergraph of diameter at most 3. More precisely, the next lemma shows that

there is a hypergraph with n vertices, at least $2\epsilon n^k$ edges, and every subhypergraph of diameter at most 3 has at most $c_k^{-1}\epsilon^{k+1}n^k$ edges. Hence $P_k(n,\epsilon,3) \geqslant (\epsilon n^k)/(c_k^{-1}\epsilon^{k+1}n^k) = c_k\epsilon^{-k}$. Call a k-uniform hypergraph *strongly connected* if there is a tight path between any two vertices in the hypergraph, *i.e.*, the diameter of the hypergraph is finite.

Lemma 4.6. *For each integer $k \geqslant 2$, there are positive constants c_k and C_k such that the following holds. For all sufficiently large n and ϵ satisfying $n^{-1/2} \leqslant \epsilon \leqslant C_k$, there is a hypergraph H on at most n vertices with at least $2\epsilon n^k$ edges such that every subhypergraph of H with diameter at most 3 has at most $c_k^{-1}\epsilon^{k+1}n^k$ edges.*

Proof. The proof is by induction on k. We have already established the base case $k = 2$ of this lemma in the proof of Theorem 2.9. Let $C_{k+1} = 2^{-k-3}C_k$ and let $\epsilon \leqslant C_{k+1}$. Fix $\delta = 2^{k+3}\epsilon$ and $N = n/2$. Our induction hypothesis implies that there is a k-uniform hypergraph G with N vertices and $2\delta N^k$ edges such that every diameter at most 3 subhypergraph of G has at most $c_k^{-1}\delta^{k+1}N^k$ edges. So G has edge density $\alpha = 2\delta N^k/\binom{N}{k} \leqslant 4\delta \cdot k!$.

Let $G_1,\ldots,G_t$ be $t = \frac{2}{\alpha}$ random copies of G on the same vertex set $[N]$, where G_i is formed by considering a random bijection of $V(G)$ to $[N]$ picked independently of all the other G_j. The probability that a given k-tuple contained in $[N]$ is an edge of at least one of these t copies of G is

$$1 - (1 - \alpha)^t \geqslant 1 - e^{-\alpha t} = 1 - e^{-2} \geqslant 1/2.$$

By linearity of expectation, the expected number of edges which are contained in at least one of the t copies of G is at least $\frac{1}{2}\binom{N}{k}$. So we may pick $G_1,\ldots,G_t$ such that at least $\frac{1}{2}\binom{N}{k}$ of the k-tuples contained in $[N]$ are in at least one of these t copies of G.

If an edge e is in multiple copies of G, arbitrarily delete it from all G_i that contain it except one. Let G_i' be the resulting subhypergraph of G_i. Introduce new vertex sets $V_1,\ldots,V_t$, each of size N/t, and define a $(k+1)$-uniform hypergraph H on $[N] \cup V_1 \cup \cdots \cup V_t$ as follows. The edges are those $(k+1)$-sets which for some i contain an edge of G_i' together with a vertex of V_i. The number of vertices of H is $2N = n$ and the number of edges is at least

$$(N/t)\frac{1}{2}\binom{N}{k} = \frac{\alpha N}{4}\binom{N}{k} = \frac{1}{2}\delta N^{k+1} = 2\epsilon n^{k+1}.$$

Note that every edge of H has exactly one vertex in some V_i. Let H' be a diameter at most 3 subhypergraph of H. Since the G_i' have distinct edges, the vertex set of any strongly connected subhypergraph of H, and hence of H', intersects at most one V_i. Therefore, there is an i such that $V(H') \subset V_i \cup [N]$ and $E(H') \subset V_i \times E(G_i')$. Since each edge of H' has exactly one vertex in V_i, note that if we delete from any tight path in H' all the vertices of V_i we obtain a tight path in G_i'. Therefore the subhypergraph of G_i' whose edges are those which are subsets of edges of H' also has diameter at most 3. Since G_i' is a subhypergraph of a copy of G, any diameter 3 subhypergraph of G_i' has at most $c_k^{-1}\delta^{k+1}N^k$ edges. Thus, using that $n = 2N$ and $1/t = \alpha/2 \leqslant 2\delta \cdot k!$, we obtain that H' has at most

$$|V_i|c_k^{-1}\delta^{k+1}N^k = (N/t)c_k^{-1}\delta^{k+1}N^k \leqslant 2 \cdot k!c_k^{-1}\delta^{k+2}N^{k+1} = 2^{k^2+4k+6}k!c_k^{-1}\epsilon^{k+2}n^{k+1}$$

edges. Letting $c_{k+1} = 2^{-k^2-4k-6}c_k/k!$ completes the proof by induction. $\qquad\square$

Essentially the same proof gives the following lemma. The only difference is the base case $k = 2$ of the induction is given by taking H to be a disjoint union of cliques of equal size.

Lemma 4.7. *For each integer $k \geqslant 2$, there are constants c_k and C_k such that the following holds. For all sufficiently large n and ϵ satisfying $n^{-1} \leqslant \epsilon \leqslant C_k$, there is a hypergraph H on n vertices with $2\epsilon n^k$ edges such that every strongly connected subhypergraph of H has at most $c_k^{-1}\epsilon^k n^k$ edges.*

The hypergraph H in the previous lemma demonstrates the following corollary.

Corollary 4.8. $P_k(n, \epsilon, d) \geqslant c_k \epsilon^{1-k}$ *for $n^{-1} \leqslant \epsilon \leqslant C_k$ and any d.*

5. Concluding remarks

In the previous section we established both upper and lower bounds on $P_k(n, \epsilon, d)$. We think the lower bound in Theorem 4.5 is best possible up to a constant factor, *i.e.*, all but at most ϵn^k edges of every n-vertex k-uniform hypergraph can be partitioned into $O(\epsilon^{-k})$ subhypergraphs of diameter 3. We also believe that Corollary 4.8 is tight, and for each integer $k \geqslant 3$ there is another integer $d(k)$ such that $P_k(n, \epsilon, d(k)) = O(\epsilon^{1-k})$. Note that Theorem 1.1 shows that both our conjectures hold for graphs ($k = 2$).

Improving our upper bound on $P_k(n, \epsilon, 3)$ would also be interesting. One possible way to do so is to show that there are many copies of the hypergraph H^k in every k-uniform hypergraph on n vertices with edge density ϵ. This problem is closely related to the well-known conjectures of Simonovits [14] and Sidorenko [13], which suggest that, for any bipartite graph H, the number of its copies in any graph G on n vertices and edge density ϵ ($\epsilon > n^{-\gamma(H)}$) is asymptotically at least the same as in the n-vertex random graph with the same edge density. So far it is known only in very special cases, *i.e.*, for complete bipartite graphs, trees, even cycles (see [13]), and recently for cubes [8]. It is tempting to conjecture that an analogous statement holds for k-uniform k-partite hypergraphs ($k \geqslant 3$). A k-uniform hypergraph is k-*partite* if there is a partition of the vertex set into k parts such that each edge has exactly one vertex in every part. The Simonovits–Sidorenko conjecture for hypergraphs would say that, for any k-partite k-uniform hypergraph H, the number of its copies in any k-uniform hypergraph on n vertices with edge density ϵ ($\epsilon > n^{-\gamma(H)}$) is asymptotically at least the same as in the random n-vertex k-uniform hypergraph with edge density ϵ. It holds for *complete* k-partite k-uniform H (Lemma 4.2 is essentially the case when all parts of H have equal size). However, as shown by Sidorenko [13], this is false in general. Nevertheless, it is still an intriguing open problem to accurately estimate the minimum number of copies of a fixed hypergraph H that have to appear in every k-uniform hypergraph on n vertices with edge density ϵ.
